CHAPTER 167

Hepatitis A Virus

Ana María Ríos

HISTORY

Hepatitis A has been recognized as a clinical entity for centuries, and large epidemics of jaundice occurred during military campaigns in ancient and modern times. During the past several decades, epidemiologic and clinical studies defined the infectious nature of the disease, which led to the differentiation of "infectious hepatitis," now designated hepatitis A.[204] Before 1970, attempts to isolate a virus associated with hepatitis A were uniformly unsuccessful, and information concerning the clinical course of infection, the fecal-oral route of transmission, and the efficacy of immunoglobulin in preventing disease was obtained from studies conducted in humans.[204,206,412] In 1973, hepatitis A virus (HAV) was identified by immune electron microscopy in stool samples of patients with hepatitis A.[133] This discovery led to the development of serologic tests that differentiate acute and resolved infections, characterization of the virus, definition of pathogenic events during infection, and further definition of the epidemiology of HAV infection. HAV has been propagated in cell culture,[91,295,395] which has led to the development and licensure of vaccines shown to be highly efficacious in preventing infection and disease in immunized individuals.[64,176]

PROPERTIES

Classification

HAV is a 27-nm, nonenveloped, positive-sense RNA virus belonging to the family *Picornaviridae*. Although HAV initially was classified in the genus *Enterovirus*, nucleotide analysis indicates that HAV is distinct from all other picornaviruses.[225,386,404] In contrast to other enteroviruses, HAV has essentially no nucleotide or amino acid homology, does not have an intestinal replication phase, replicates slowly in cell culture and rarely produces a cytopathic effect, and is relatively resistant to inactivation by heating.[87] For these reasons, HAV has been reclassified in a separate genus designated *Hepatovirus*.[255,404]

Genomic Organization and Genetic Variation

Hepatitis A is composed of an icosahedral capsid that contains a positive-sense, single-stranded RNA genome of approximately 7.5 kb in length with a single open reading frame flanked by 5′ and 3′ untranslated regions (UTR). The 5′ UTR is the most conserved region of the genome and contains an internal ribosome entry site. The open reading frame encodes a polyprotein organized into three functional regions: P1, P2, and P3. P1 is secondarily cleaved into four capsid proteins, VP1 to VP4, whereas P2 and P3 proteins encode nonstructural proteins associated with replication.[225,355,396,404]

HAV exists as a single serotype. The neutralization site appears to be conformational and derived from epitopes located on VP1 and VP3, as identified by neutralizing monoclonal antibodies.[262,292] A high degree of nucleotide conservation exists among geographically diverse human HAV isolates. However, enough genetic diversity exists to define several HAV genotypes and subgenotypes. The entire nucleic acid sequences of several HAV strains have been determined by molecular cloning, and a large number of HAV isolates have been characterized by sequencing of short genome segments.[265]

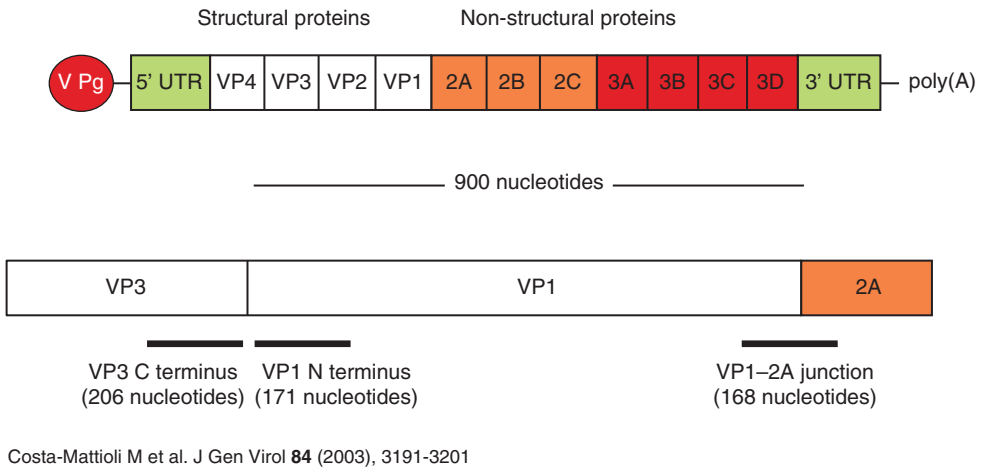
The genomic regions most commonly used to define HAV genotypes include (1) the C terminus of the VP3 region, (2) The N terminus of the VP1 region, (3) the junction of the VP1 and P2A regions, (4) the VP1-P2B regions and the entire VP1 region (Fig. 167-1).[80,265]

Sequence variation of a 168-nucleotide fragment encompassing the VP1/2A junction had initially defined seven genotypes that differ at least by 15 percent and subtypes that differ by 7 to 7.5 percent.

Six genotypes (I to VI) are now defined based on analysis of the 900 nucleotides of the complete VP1 protein. Genotypes I, II, and III, divided into subtypes A and B, infect humans. The former genotype VII was reclassified within the genotype IIB.[81,265] The other three (IV, V, and VI) appear to be restricted in their primary replication to Old World monkeys.[264,367]

The worldwide geographic distribution of HAV serotypes has been described by many reports.[80,265,308] Genotype I is the most prevalent worldwide, particularly genotype IA, which dominates in North, Central, and South America; China; Japan; Thailand; and Europe.[50,177,184,308] Subgenotype IB is reported mainly from the Mediterranean region and South Africa and is the most prevalent in Turkey.[273] Subgenotype IIIA is the most prevalent in India, Nepal, and Korea.[170,341,410] In low-endemicity areas, such as the United States and Western Europe, subgenotype IA dominates, but all genotypes have been reported.[81,265] Of note, subgenotypes IIA, IIB, and IIIB rarely have been reported.[103]

The analysis of the other genomic regions (i.e., the N terminus of the VP1, VP1-2B regions, the entire VP, and the C terminus of VP3) allows better strain discrimination. Growing sequence databases allow for the identification of the geographic origin of a given subgenotype.



Costa-Mattioli M et al. J Gen Virol **84** (2003), 3191-3201

FIGURE 167-1 ■ Genomic organization of hepatitis A virus (HAV). (See companion Expert Consult website for color version.)

This genetic variation has proved useful in identifying clusters and linking apparently sporadic cases.*

Genotype does not appear to influence the clinical presentation or outcome of infection.[2,144,170] However, two recent publications from Korea proposed that genotypes might account for differences in disease severity. A publication about a nationwide hepatitis A outbreak in Korea from 2006 to 2008 suggested that genotype IIIA infection, in contrast to genotype IA infection, might show more severe clinical manifestations.[410] Similarly, a separate study from Korea compared disease severity related to genotype in adolescents and young adults. Genotype IIIA was found to be associated with higher alanine aminotransferase (ALT) levels and longer hospitalization in a multivariate logistic regression model.[407]

HAV replicates more slowly in cell culture than other picornaviruses; wild-type virus requires many weeks of adaptation before infectious foci or HAV antigen is detected.[34,224,333] HAV produces a high ratio of defective to complete (infectious) virus both in cell culture and during infection.[44,404] Cell culture adaptation is associated with mutations in nonstructural proteins and the 5′ nontranslated region.[120,122] Mutations in the VP1/2A and 2C genes are associated with attenuation, and virulence can be restored if genes from the wild-type virus are reintroduced.[121] Cell culture–adapted HAV rarely produces a cytopathic effect, although cytopathic strains have been isolated and serve as a useful model for laboratory studies.[88,267] Adaptation also results in loss of virulence (attenuation) when it is evaluated in the chimpanzee model of infectivity.[187] Cell culture systems that are more permissive to replication of virulent wild-type virus have been reported.[132,201]

The HAV virion appears to be extremely stable, although the molecular determinants of this characteristic are not known. HAV is stable in the environment, with only a 100-fold decline in infectivity when it is stored for longer than 4 weeks at room temperature.[87,244,245,288] The virus retains infectivity when it is treated with nonionic detergents, organic solvents, and low pH at 38° C (100.4° F) for 90 minutes.[87,254] HAV is more resistant than poliovirus to heat in that it is inactivated only partially at 60° C (140° F) for 1 hour.[87] Temperatures of 85° to 95° C (185° to 203° F) for 1 minute are required for complete inactivation of HAV in foods such as shellfish.[87,255] HAV is inactivated completely by formalin (0.02% at 37° C [98.6° F] for 72 hours) but appears to be relatively resistant to free chlorine, especially when the virus is associated with organic matter.[233,331] For general-purpose disinfection, a 1:100 dilution of 5 percent sodium hypochlorite (i.e., household bleach) in tap water inactivates HAV in most situations.[64,129]

*References 10, 101, 167, 172, 263, 306.

EPIDEMIOLOGY

Routes of Transmission

Routes of HAV transmission are determined by the timing and location of virus replication, circulation, and excretion during infection. HAV replicates in the liver, is excreted in bile, and is found in highest concentration in stool (up to 10^8 infectious particles per milliliter).[355] The highest concentration in stool occurs during the 2-week period before jaundice develops or liver enzymes become elevated, followed by a rapid decline after jaundice appears (Fig. 167-2).[133,338,355] Children and infants may shed HAV for longer periods than do adults. Through the use of polymerase chain reaction (PCR) to amplify viral nucleic acid, HAV RNA has been detected in the stool of infected neonates for as long as 6 months after infection, and some studies have shown excretion in older children and adults 1 to 3 months after the onset of clinical illness.[176,310,409] Chronic shedding of HAV does not occur; however, virus may be present in stool during relapsing illness (see the section on relapsing hepatitis A).[337] Viremia occurs during the prodromal stage of infection and extends through the period of liver enzyme elevation (see Fig. 167-2), with virus concentrations several orders of magnitude lower than those in stool.[43,77,205,225] In experimentally infected animals, HAV can be detected in saliva during periods of peak excretion

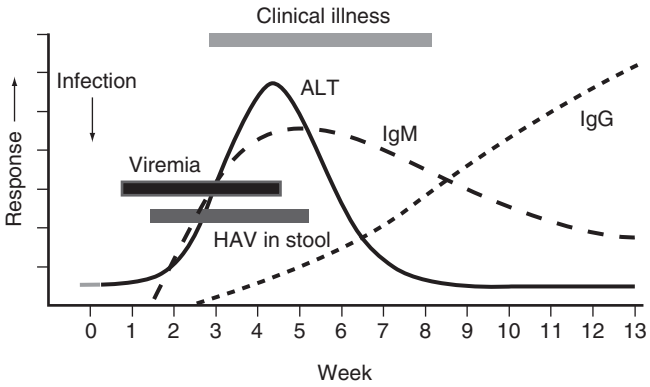


FIGURE 167-2 ■ Immunologic, virologic, and biochemical events during the course of a typical hepatitis A virus *(HAV)* infection. *ALT,* Alanine aminotransferase; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

in stool.[77] HAV also has been detected in the saliva of infected patients with concurrent HAV viremia through HAV RNA with identical serum and saliva sequences.[231] The simplicity of obtaining saliva allows the recommendation of the use of saliva for investigation of outbreaks.[6,7] The saliva as an extrahepatic site of early HAV replication could create a potential risk for saliva-transmitted infection.[5]

Detection of HAV antigen in stool by enzyme immunoassay or detection of HAV RNA in serum or stool by PCR does not demonstrate that an infected person is infectious, because these assays may detect defective as well as infectious viral particles. Nucleic acid amplification by immunocapture PCR requires the presence of intact virus,[46,187] and HAV RNA may be detected in stool for months with immunocapture PCR. However, the period of infectivity appears to be shorter than the period when HAV RNA can be detected in stool. Data from epidemiologic studies suggest that peak infectivity occurs during the 2 weeks before the onset of symptoms. For practical purposes, both children and adults with hepatitis A can be assumed to be noninfectious 1 week after jaundice appears.

Because of the high concentration of virus in the stool of infected persons, HAV transmission occurs primarily by the fecal-oral route, usually by person-to-person transmission in households and extended-family settings and between sexual contacts.[344] Person-to-person transmission results in high rates of infection in young children in developing countries and has been the predominant mode of transmission in the United States, particularly during community-wide outbreaks, as well as in outbreaks in child care centers.[25,38] HAV can remain infectious in the environment,[245] and fecal contamination of food or water can result in common-source outbreaks. HAV has been transmitted by transfusion, but such transmission occurs rarely because the blood donation must occur during the early prodromal stage of the disease or from an asymptomatic person who is viremic.[221] In the United States, nucleic acid amplification tests such as PCR now are applied to screening of source plasma used for the manufacture of plasma-derived products. These assays are sufficiently sensitive to remove most units that have HAV, and serosurveillance for HAV infections among clotting factor recipients in the United States indicates that HAV infections are now rare in this risk group.[60]

Two published case reports have described intrauterine transmission of HAV during the first trimester that resulted in fetal meconium peritonitis.[218,246] After delivery, both infants were found to have a perforated ileum. The risk for transmission to newborns by pregnant women in whom hepatitis A develops in the third trimester of pregnancy appears to be low.[259,319,362] Newborns who acquire HAV infection in this manner or from a transfusion usually are asymptomatic, and the infection is detected by the development of hepatitis A in hospital staff or other persons having contact with the infant.[310,389] A couple case reports have described vertical HAV transmission associated with jaundice and raised liver enzymes during the first weeks of life with uneventful improvement.[123,303] HAV RNA was detected in breast milk of two of three women with acute HAV infection in whom anti-HAV immunoglobulin (Ig)M and IgG were detected in serum and breast milk, as well as HAV RNA in serum. Transmission by breast milk has not been demonstrated.[97]

Patterns of Disease Worldwide

Worldwide, the endemicity of HAV infection differs markedly among and within countries (Fig. 167-3).[182]

Patterns of HAV infection can be differentiated, each being characterized by distinct age-specific profiles of prevalence of antibody to HAV (anti-HAV), incidence of hepatitis A, and prevailing environmental (hygienic and sanitary) and socioeconomic conditions (Fig. 167-4).[23,25,157,181,182]

In areas with a high endemic pattern of infection, represented by the least developed countries (i.e., parts of Africa, Asia, and Central and South America), poor socioeconomic conditions allow HAV to spread readily (see Fig. 167-3). Most persons are infected as young children, and essentially the entire population is infected before reaching adolescence, as demonstrated by the age-specific prevalence of anti-HAV (see Fig. 167-4).[22,83,181,325,368] Because virtually all HAV infections occur in age groups in which asymptomatic infection predominates, reported disease rates may be low and outbreaks rare.

In areas of intermediate endemicity, HAV is not transmitted as readily because of better sanitary and living conditions, and the predominant age at infection is older than that in highly endemic areas (see Figs. 167-3 and 167-4).[73,181] Paradoxically, the overall incidence and average age of reported cases often increase because high levels of virus circulate in a population that includes many susceptible older children, adolescents, and young adults, in whom symptoms are likely to develop with HAV infection.[155] Large common-source outbreaks also can occur because of the relatively high rate of virus transmission and the large number of susceptible persons, especially among those of higher socioeconomic levels. Such an outbreak occurred in Shanghai in 1988, with more than 300,000 cases associated with the consumption of

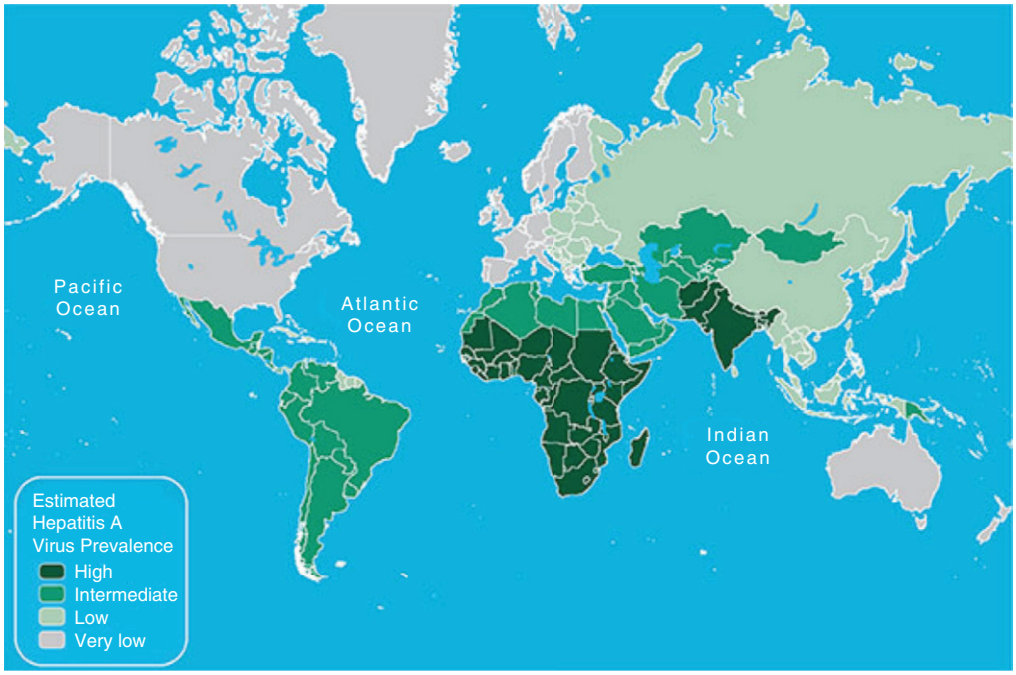

FIGURE 167-3 ■ Estimated geographic distribution of patterns of endemicity of hepatitis A virus (HAV) infection. The distribution was generalized from the best available data. (See companion Expert Consult website for color version.)

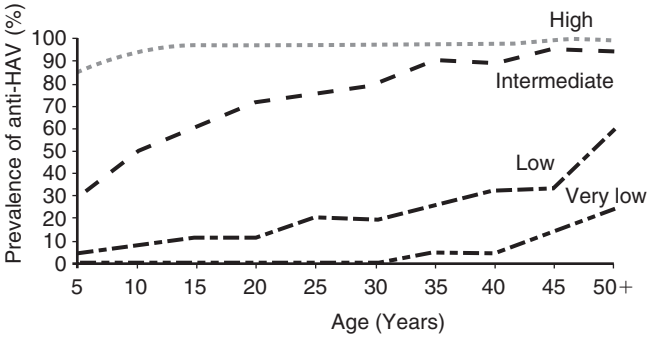

FIGURE 167-4 ■ Patterns of hepatitis A virus *(HAV)* infection worldwide.

contaminated clams.[160] Nonetheless, person-to-person transmission in community-wide epidemics continues to account for much of the disease in these countries.[382]

Considerable hepatitis A–related morbidity and associated costs can occur, even in developing countries. Hepatitis A is reported to account for 50 to 60 percent of all acute viral hepatitis cases among children in Pakistan, and 232 children with fulminant hepatic failure secondary to hepatitis A were admitted to one tertiary care referral hospital in Karachi during a 9-year period.[321] Hepatitis A was the etiology of the fulminant hepatitis of two thirds of the children treated at two hospitals in Argentina during a 15-year period; and in one of these hospitals performing liver transplantation, a third of the liver transplantations in children were required because of fulminant hepatitis A.[74] Another small series from Turkey indicated that HAV was the most common identifiable cause of acute liver failure among children, accounting for 26 percent of cases.[18]

In most areas of North America and Western Europe, sanitary and hygienic conditions are such that the endemicity of HAV infection is low (see Figs. 167-3 and 167-4). Relatively fewer children are infected, and disease often occurs in the context of community-wide and child care center outbreaks and occasionally as common-source outbreaks.[28,149,294,324,358] In some regions (e.g., Scandinavia), the endemicity of HAV infection is very low and disease occurs almost exclusively in defined risk groups, such as travelers returning from areas where HAV infection is endemic or illicit drug users.[41]

Some changes have occurred in the epidemiologic trends and patterns of hepatitis A infection around the world related to vaccine A implementation, socioeconomic progress, and improvement in hygiene measures.*

Shifts in age-specific prevalence patterns indicating a transition from high to intermediate endemicity are occurring in many parts of the world (see Fig. 167-4). As this transition occurs, marked variations in hepatitis A epidemiology are seen among countries and within countries and cities, with some areas displaying a pattern typical of high endemicity and others of intermediate endemicity (see Fig. 167-3).[25,155,182]

Systematic review and meta-analysis of published data using IgG anti-HAV seroprevalence data between 1990 and 2005 from different world regions indicated that high-income regions (i.e., Western Europe, Australia, New Zealand, Canada, the United States, Japan, the Republic of Korea, and Singapore) remain as having a very low HAV endemicity levels and a high proportion of susceptible adults. The low-income regions (i.e., sub-Saharan Africa and parts of South Asia) still present high endemicity levels and almost no susceptible adolescents

*References 182, 192, 209, 215, 216, 257, 369.

and adults, and most middle-income regions (i.e., Asia, Latina America, Eastern Europe, and the Middle East) demonstrated a mix of intermediate and low endemicity levels.[182]

Patterns of Disease in the United States

The epidemiology of hepatitis A in the United States has been altered profoundly by the introduction of hepatitis A vaccines, with a significant reduction as a vaccine-preventable infectious disease (Fig. 167-5A). Rates have declined sharply since the mid-1990s. In 2010, 1670 cases were reported to the Centers for Disease Control and Prevention (CDC), representing a 94 percent decline in contrast to rates from 1990 to 1997 and significantly lower than previous incidence nadirs.[68,70] However, national surveillance systems collect data on symptomatic cases, and incidence models indicate that most infections are not symptomatic. One such analysis estimated that an average of 271,000 infections occurred per year during 1980 to 1999—10.4 times the reported number of symptomatic cases.[12] With use of similar modeling methodology, an estimated 17,000 infections occurred in 2010 (see Figure 167-5B).[69]

Variation by Age and Race or Ethnicity

Historically, the highest hepatitis A rates were reported among children 5 to 14 years of age, with approximately one third of cases occurring among children younger than 15 years.[58] Because many young children have unrecognized or asymptomatic infection, they also are likely to represent a major reservoir for HAV transmission. Incidence models indicated that during the 1980s

FIGURE 167-5 ■ **A,** Reported number of hepatitis A cases, United States, 2000-2010. **B,** Hepatitis A incidence rates (per 100,000 population) based on cases reported to the Centers for Disease Control and Prevention (1980-2010).

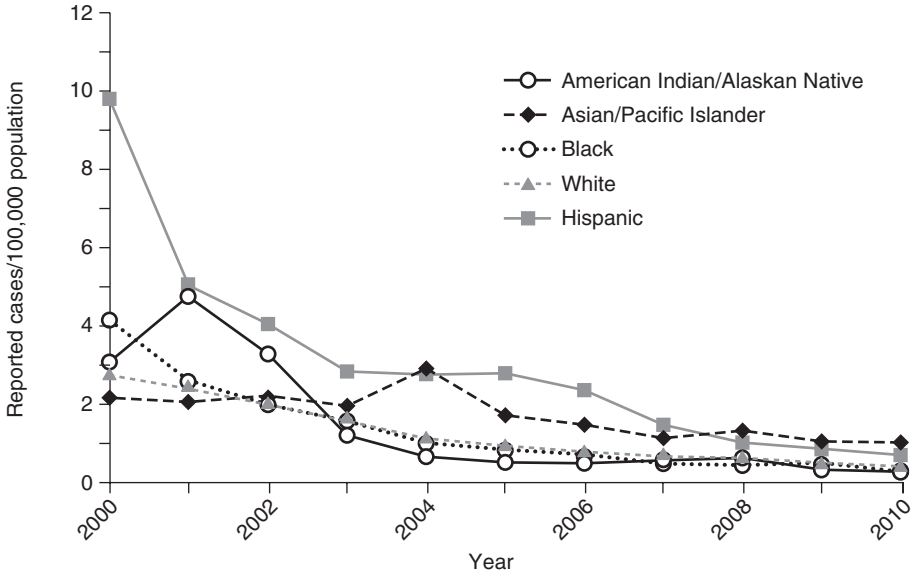
and 1990s, more than half of HAV infections occurred among children younger than 10 years of age, most of whom were younger than 4 years.[12] Since the mid-1990s, decreases in rates among children have been greater than among adults, and the proportion of cases among children dropped from 35 percent in the prevaccine era to 19 percent in 2003.[388]

From 2002 to 2010, rates were similar and low among persons in all age groups (<1.0 cases/100,000 population). In 2010, the range was from 0.23 to 0.74 cases/100,000 population.[68,70] The highest rates were for persons 15 to 24 years of age (0.74 cases/100,000 population) and the lowest rates were among children younger than 9 years of age (0.3 cases/100,000 population).[70]

Among racial and ethnic groups, before the use of hepatitis A vaccine, rates among Native Americans and Alaska Natives were more than 10 times the rates in other racial and ethnic groups, and rates among Hispanics were approximately three times higher than among non-Hispanics. These disparities have lessened or disappeared in the era of routine childhood vaccination, with rates among Hispanics in 2003 approximately twice those among non-Hispanics (86% decline in contrast to 1990 to 1997); and rates among Native Americans and Alaska Natives were the same as or lower than those among other ethnic groups.[388] In 2010, the rate for hepatitis A among Hispanics was 0.7 cases/100,000 population, the lowest rate ever reported for this group. Rates among Native Americans and Alaska Natives are now the same as or lower than those among other ethnic groups. The 2010 rate of hepatitis A among Native Americans and Alaskan Natives was the lowest ever recorded (0.2/100,000 population) (Fig. 167-6).[70] Seroprevalence of antibody to HAV (anti-HAV) in the population reflects immunity to either previous infection or vaccination. As determined by the National Health and Nutrition Examination Survey (NHANES); the overall seroprevalence on anti-HAV in United States was 34.9 percent (95% confidence interval [CI], 33.1, 36.7) during 1999 to 2006.[195,197] Seroprevalence among children has increased from 8 percent (6.3% to 10.1%) in 1988 to 1994 to 35.3 percent in 2007 to 2008, which probably reflects increased immunization of children and others.[251] For U.S.-born children 6 to 19 years of age, the strongest factor associated with seroprevalence was residence in vaccinating states. Among U.S.-born adults aged older than 19 years, the overall age-adjusted seroprevalence of anti-HAV was 29.9 percent (95% CI, 28.3, 31.5) during 1999 to 2006, which was not significantly different from the seroprevalence during 1988 to 1994 (32.2%; 95% CI 30.1, 34.4).[195,197] Among U.S.-born adults (40 years of age and older), HAV antibody prevalence decreased from 1988 to 1994 to 2003 to 2006, which may reflect lower rates of infection resulting from reduced exposure to the virus because of higher rates of immunization among younger age groups.[251] The decrease in seroprevalence in the adult population reflects the replacement of adults who were exposed naturally to HAV in the past by an adult population who are neither vaccinated nor previously exposed.[167] For all of the periods, the Mexican-American population had a significantly higher prevalence of HAV antibody in contrast to the non-Hispanic white and non-Hispanic black populations among both children 6 to 19 years of age and adults 20 years of age and older. This is probably a reflection of higher rates of vaccination within this subgroup, but also a continued greater exposure to natural infection from travel to or visitors from Mexico, where the disease is endemic.[251]

Geographic Variation

Analyses of national surveillance data collected during the 1980s and 1990s showed striking regional variation in the incidence of hepatitis A. The national average



Source: National Notifiable Diseases Surveillance System (NNDSS)

FIGURE 167-6 ■ Hepatitis A incidence, United States, by race and ethnicity, 2000 through 2010. (Data from the Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System, Atlanta, Ga.)

incidence was approximately 10 cases/100,000 persons per year during 1987 to 1997, with the highest rates and almost all cases consistently occurring in a limited number of states and counties concentrated in the western and southwestern United States.[57] Approximately two thirds of cases were reported from the 17 states with the highest rates, even though only one third of U.S. residents lived in these states. With the implementation of routine vaccination of children in these states in 1999, rates equalized across the country,[388] with significantly greater reductions in incidence in areas where vaccination was recommended.[314,388]

HAV infection rates are now the lowest ever reported and similar in all regions. The rate of acute hepatitis A declined from 1.5 cases/100,000 population to 0.54/100,000 population during 2005 to 2010.[70]

In 2010, the case rate ranged from 0.1 case/100,000 population (Arkansas, Mississippi, and South Dakota) to 1.0 case/100,000 population (Arizona).[68]

Potential Sources of Infection

The distribution of potential HAV exposures among cases for which information regarding exposures is available has changed in the vaccination era. The proportion of cases attributable to household or sexual contact with a person who has hepatitis A, the most commonly reported potential source of infection, has declined as routine hepatitis A vaccination of children has increased, from 15 to 25 percent to 5.6 to 7.3 percent of reported cases in 2009 and 2010.[61,63,67,68] The number of international travel–associated cases has remained approximately the same; but as overall incidence declined, the proportion of cases attributable to this exposure has risen to 14 to 15 percent reported in 2009 to 2010.[67,68] In sites conducting enhanced hepatitis surveillance during 2005 to 2007 as part of the Emerging Infection Program of the CDC; the most frequent (46%) potential source of infection among persons reported with HAV disease was travel outside of the United States and Canada. These cases mostly reflected persons who traveled, but also included some who were exposed to a traveler but did not travel themselves.[196] As in previous years, most travel-related cases (85%) were associated with travel to Mexico, Central America, and South America.[196,325]

Recognized foodborne outbreaks account for a small proportion of cases in most years (3% to 5%), but large outbreaks such as those associated with contaminated green onions in 2003 have increased the proportion of cases associated with food in some years to as high as 16 percent.[10,61,63,393] In 2010, the linkage to an outbreak could be determined in 10 percent of the reported cases for which this information was available.[68]

Cyclic outbreaks occur among men who have sex with men (MSM) and users of injecting and noninjecting drugs; during outbreak years, this exposure can account for 10 to 15 percent of nationally reported cases.*

In 2010, only 5 percent of the case reports with information available about sexual practices indicated sex with another man and only 2 percent reported use of injection drugs.[68] Nearly 50 percent of patients with hepatitis A do not have a recognized source of infection[61,63,67,68] but might be contacts of persons, especially children, with asymptomatic infection.

Community-Wide Epidemic

Historically, most cases of hepatitis A in the United States occurred in the context of community-wide epidemics, during which infection is transmitted from person to person in households and extended-family settings.[28] Once initiated, these epidemics often persisted for several years and proved difficult to control[283,329] even when attempts were made to vaccinate some portion of the population rapidly.[16,85] Children played an important role in HAV transmission during these epidemics. In communities with historically the highest hepatitis A rates, as exemplified by Native American and Alaska Native communities, the pattern of transmission was similar to that found in countries with an intermediate endemicity of hepatitis A infection (see the discussion on patterns of disease worldwide).[49,102,212,328,401] The best explanation for these observations is that asymptomatic transmission was occurring in susceptible young children at low levels during interepidemic periods until a cohort of susceptible children became large enough to sustain a community-wide outbreak.[328,339] Asymptomatic transmission among children also has been important in sustaining outbreaks in areas with consistently elevated rates. During community-wide outbreaks, serologic studies of members of households with an adult case and no identified source found that 25 to 40 percent of contacts younger than 6 years of age had serologic evidence of having had recent HAV infection.[306,344] In one of these studies, 52 percent of households of adults without an identified source of infection included a child younger than 6 years and the presence of a young child was associated with household transmission of HAV.[344] In this study, transmission chains were identified involving as many as six generations and more than 20 cases. With the advent of routine vaccination of children, community-wide outbreaks have largely ceased. Community-wide outbreaks that have been sustained by transmission among adults in high-risk groups continue to be identified, and novel strategies to provide vaccination in settings such as jails have had some success.[61,263,274,359,386]

EPIDEMIOLOGY OF HEPATITIS A IN SPECIFIC SETTINGS

Child Care Centers

The role of children with asymptomatic infection has been recognized in outbreaks in child care centers since the 1970s.[322,323] Because infection in children usually is mild or asymptomatic, these outbreaks often are not recognized until adult contacts (usually parents) become ill.[159] Outbreaks rarely occur in centers that do not have children in diapers and occur more commonly in larger

*References 61, 63, 82, 143, 162, 171, 315.

centers.[159] Both poor hygiene in these children and the need for staff to handle and change diapers contribute to spread. Despite the occurrence of outbreaks when HAV is introduced into a child care center, studies of child care center employees do not show a significantly increased prevalence of HAV infection in contrast to control populations.[140,180] On occasion, outbreaks in child care centers can be the source of more extensive transmission within a community.[104,158,378] However, most disease within child care centers probably reflects transmission from the community. Hepatitis A outbreaks within child care centers have become unusual events in recent years and are likely to be eliminated as routine vaccination of all young children is implemented.

Other Groups and Settings

Hepatitis A cases in school children usually reflect disease that has been acquired in the community. However, multiple cases among children within a school may indicate a common-source outbreak.[172] Historically, HAV infection was endemic in institutions for the developmentally disabled; but with smaller facilities and improved conditions, the incidence and prevalence of infection have decreased, and outbreaks rarely are reported in the United States.[349]

During the past 2 decades, outbreaks have been reported with increasing frequency in illicit drug users in North America, Australia, and Europe.* In the United States, these outbreaks often have occurred in the context of a large community-wide outbreak; in the past decade, they frequently have involved users of injected and noninjected methamphetamine, who may account for as many as 30 percent of reported cases in these communities during outbreaks.[28,171,173,263,386] Cross-sectional serologic surveys have demonstrated that injection drug users have a higher prevalence of anti-HAV than the general U.S. population.[178,384] Transmission among injection drug users probably occurs through both percutaneous and fecal-oral routes.[173]

Hepatitis A outbreaks in MSM have been reported frequently, most recently in urban areas in the United States, Canada, Europe, and Australia.† These outbreaks may occur in the context of an outbreak in the larger community.[28] Some studies conducted during outbreaks and seroprevalence surveys among MSM identified specific sex practices associated with illness, whereas others have not demonstrated such associations.‡

Transfusion-related hepatitis A rarely occurs because HAV does not result in chronic infection and blood donors are screened for elevated aminotransferase levels. Currently, nucleic acid amplification tests also are used to screen source plasma used in the manufacture of plasma-derived products. However, during the mid-1990s, outbreaks were reported in Europe and the United States in patients who received factor VIII and factor IX concentrates prepared by solvent-detergent treatment to inactivate lipid-containing viruses.[236,342] HAV is resistant to solvent-detergent treatment, and contamination presumably occurred from plasma donors with hepatitis A who donated during the incubation period. The risk for acquiring infection in patients with hemophilia is not known, although data from one serologic survey of hemophiliac patients suggested that they might be at increased risk for acquisition of HAV infection.[232] However, no HAV infections attributed to blood products were identified in an analysis of serosurveillance data collected from 140 hemophilia treatment centers in the United States between 1998 and 2002, suggesting that improved viral inactivation procedures, donor screening, and increased hepatitis A vaccine coverage among clotting factor recipients can reduce the risk for transmission of HAV to recipients of clotting factors.[60] Transmission related to blood transfusions also has resulted in nosocomial outbreaks in neonatal intensive care units.[194,272,310] Hepatitis A has been reported in adult cancer patients treated with lymphocytes that apparently were incubated in serum from a donor with HAV infection, although the patient source was not identified.[391]

Nosocomial transmission from adult patients to health care workers usually has been associated with fecal incontinence of the patient.[153,281] Such transmission is a rare event, however, because most patients with hepatitis A are hospitalized after the onset of jaundice, when infectivity is low.[130,338] Health care workers have not been found to have an increased prevalence of anti-HAV in contrast to control populations in serologic surveys conducted in the United States.[148]

Persons from developed countries who travel to developing countries with a high, transitional, or intermediate endemicity of HAV infection are at substantial risk for acquiring hepatitis A (see Fig. 167-3).[182,325,346]

Hepatitis A infection is one of the most common vaccine-preventable infections acquired during travel.[325] A more recent study of Swiss travelers estimated the risk to be 6 to 30 cases/100,000 person-months of stay in developing countries among persons who did not receive immunoglobulin or vaccine before departure.[261] The risk is higher among travelers staying in areas with poor hygienic conditions,[210] it varies according to the region and the length of stay, and it appears to be increased even among travelers who reported staying in urban areas or luxury hotels.[325,346] In some European countries, returning international travelers with hepatitis A account for a substantial proportion of reported cases (16% to 40%).[72,397] In the United States, the proportion of cases attributed to recent international travel has increased from 5 to 15 percent.[67,68]

The potential for new foodborne outbreaks around the world has been enhanced with the world globalization by importation of food products from countries where hepatitis A remains endemic to countries with low endemicity. This has been nicely demonstrated during recent outbreak investigations of hepatitis A infection, including the multistate outbreak associated with semidried tomatoes in Australia during 2009[112] and similar outbreaks in the Netherlands[289,290] and France during 2010.[146]

Foodborne hepatitis A outbreaks are now recognized relatively infrequently in the United States and are

*References 56, 162, 171, 173, 274, 315, 327, 359, 386.
†References 39, 53, 82, 143, 320, 347, 364, 365.
‡References 31, 82, 84,165, 188, 384.

associated most commonly with contamination of food during preparation by a food handler with HAV infection. However, persons who work as food handlers are not at increased risk for acquiring hepatitis A because of their occupation. Food contaminated before retail distribution, such as lettuce or fruits contaminated at the growing or processing stage, has been recognized as the source of hepatitis A outbreaks.* Outbreaks related to contaminated shellfish, commonly noted in the past,[105,107,277,293] have become increasingly uncommon but occasionally are identified.[32] Since the large multistate outbreaks linked to oysters in 2005[32] and the one linked to green onions in 1998 through 2003,[101,393] no large outbreaks have been detected in the United States. No water-borne hepatitis A outbreaks in the United States have been reported since the 1980s; earlier outbreaks were linked to sewage contamination or inadequate treatment of water.†

Control of food outbreaks usually requires intensive public health effort.[94] HAV foodborne disease investigation with direct food testing through HAV RNA molecular techniques has made the recovery of implicated food faster and more efficient, as was demonstrated during the investigation of the large multistate outbreak of hepatitis A caused by consumption of contaminated oysters in the United States in 2005.[32] Molecular epidemiology through sequencing of outbreak strains has been demonstrated to be is an excellent tool for the investigation of HAV infection outbreaks within the United States and European countries.‡

PATHOLOGY AND PATHOGENESIS

Pathology

The light microscopic findings in acute hepatitis A, which include inflammatory cell infiltration, hepatocellular necrosis, and liver cell regeneration, are common to all forms of acute viral hepatitis. These histologic findings vary with the stage and severity of hepatitis. Early biopsy specimens generally show portal infiltration by lymphocytes, plasma cells, and macrophages positive for periodic acid–Schiff.[108,357] Spotty or focal necrosis, as evidenced by balloon degeneration, shrinkage, and fragmentation of hepatocytes, is seen commonly.[108] HAV antigen is found primarily in the cytoplasm of hepatocytes, but it also can be found in liver macrophages. However, because HAV infection is self-limited and does not result in chronic liver disease, liver biopsy rarely is indicated (see the discussion on treatment).

Differences have been noted in light microscopic findings of hepatitis A and other forms of viral hepatitis, particularly hepatitis B. In addition to degeneration of hepatocytes in the perivenular area, periportal inflammation and destruction of hepatocytes adjacent to the portal area may be more pronounced than in hepatitis B.[1,278,357] Findings in some patients, including extension of the inflammatory infiltration from the periportal area into the hepatic parenchyma and disruption of the limiting plate, may be difficult to distinguish from those of chronic hepatitis.[1,108] Cholestasis may be more prominent than in hepatitis B.[316]

The histologic findings in fulminant hepatitis A are indistinguishable from those in other forms of fulminant viral hepatitis. Examination of pathologic specimens shows massive hepatic necrosis, abnormal architecture of surviving hepatocytes, and a diffuse inflammatory response.[199] Viral antigen can be found in pathologic specimens.

Pathogenesis

The mechanism by which HAV crosses gastrointestinal epithelium and infects liver cells has not been completely established. Previous studies have shown that HAV-IgA complex can translocate across epithelial cells and that HAV-IgA complexes are taken up by hepatocytes through the asialoglycoprotein receptor.[113,114] In this model of HAV infection, virus would first infect gastrointestinal cells and then be transported into the enterohepatic circulation as part of an HAV-IgA complex, with subsequent selective uptake by hepatocytes. HAV is able to bind to human cells through a specific cellular receptor inserted into the plasma membrane, and DNA that encodes this receptor (huhavcr-1) has been identified in many human tissues.[131] HAVCR-1 was first discovered as the cellular receptor for HAV (HAVcr-1) in African green monkeys in 1996.[186] This cellular receptor is a member of the T-cell immunoglobulin mucin (TIM, also known as TIM-1) gene family. It appears to regulate the size and effector functions of T cells and also might play a role in the development of atopy.[247] The relationship of TIM1 and atopy with HAV exposure is important, and various epidemiologic studies around the world (in Italy, Denmark, Australia, Korea, and Turkey) have shown lower prevalence of allergy and asthma among the HAV-seropositive individuals in contrast to HAV-seronegative individuals.[242,243] Immunoglobulin (Ig)A is a natural ligand of HAVCR-1, and the association of IgA with HAVCR1 enhances virus receptor activity with synergistic effect in virus-receptor interactions.[353]

HOST INNATE AND ADAPTIVE IMMUNE RESPONSES

Cellular Immune Response

Unlike other picornaviruses, infection of cultured cells with wild-type HAV has no cytopathic effect. The general assumption is that HAV infection also is noncytopathic in vivo and therefore the cytopathic changes in the liver associated with hepatitis A are immune mediated. HAV is able to suppress interferon (INF)-β gene expression in the initial stages of infection, which might facilitate prolonged viral production and infection of neighboring cells.[134] This could be explained in part by a disruption in the signaling through the Toll-like receptor 3 pathway.[240,298] A recent research study demonstrated that

*References 10, 101, 105, 172, 270, 301, 309, 394.
†References 30, 37, 42, 47, 98, 142, 233.
‡References 32, 112, 146, 167, 289, 365.

the interaction between HAV and its receptor HAVCR1 inhibits CD4 T-cell regulatory cell function, resulting in an immune imbalance allowing viral expansion with limited hepatocellular damage during the early phase of infection, which is characteristic of HAV infection.[235] Symptoms and biochemical evidence of liver injury do not occur at the time of maximum virus replication and fecal shedding (during the late incubation period). Rather, liver injury is associated closely with viral clearance. $CD8^+$, class 1–dependent, cytotoxic, and virus-specific T cells that are capable of producing IFN-γ are present in the circulation and the liver.[139,371] Additional inflammatory cells, recruited to the site of infection by IFN-γ and other cytokines secreted by $CD8^+$ cells, may be responsible for much of the liver injury. Complement has been shown to bind to HAV capsid proteins, and serum complement levels drop during infection, but whether complement-mediated cellular injury occurs is unclear.[239] The mechanism by which infection is resolved remains uncertain.

Humoral Immune Response

Unlike the situation with hepatitis C, the adaptive immune response to HAV is robust and extremely effective in eliminating the virus. Neutralizing antibodies to the virus (anti-HAV) generally appear in the serum concurrent with the earliest evidence of serum aminotransferase elevation and hepatocellular injury (see Fig. 167-2).

Antibodies directed against conformational epitopes displayed on intact virions as well as empty viral capsids are produced during the later stages of infection (see the section on genomic organization and genetic variation). Virus-specific IgM and IgG and IgA antibodies are present in serum; IgM anti-HAV generally can be detected at the onset of symptoms (see Fig. 167-2).[240]

CLINICAL MANIFESTATIONS

Similar to other forms of viral hepatitis, the clinical manifestations of HAV infection are variable and range from asymptomatic anicteric infection to symptoms of acute hepatitis, including fever, malaise, anorexia, nausea, vomiting, right upper quadrant pain, and jaundice. The likelihood of having symptomatic HAV infection and the severity of the illness are related to the age of the patient. In early childhood, infection usually is asymptomatic, whereas infection in adulthood generally is accompanied by symptoms. The diagnosis of hepatitis A must be confirmed by serologic testing because no constellation of symptoms is pathognomonic of the disease.

Incubation Period

The average incubation period is 28 to 30 days but can range from 15 to 50 days.[204] The average incubation period has been reported to be shorter in patients who acquired HAV infection by parenteral transmission from contaminated blood products and in chimpanzees infected parenterally than in those infected orogastrically.[239,330]

Spectrum of Illness

HAV infection, confirmed by the detection of IgM anti-HAV in serum, can be inapparent (asymptomatic, with no elevation in serum aminotransferase levels), subclinical (asymptomatic, with elevation of serum aminotransferase levels), or clinically evident (with symptoms). Specific symptoms of liver dysfunction include jaundice and dark urine caused by hyperbilirubinemia. However, symptomatic hepatitis A without jaundice (anicteric) does occur. Nonspecific symptoms of acute hepatitis A can include fever, myalgia, anorexia, nausea, right upper quadrant pain or discomfort, diarrhea, and pruritus.

Many acute HAV infections, particularly inapparent and subclinical infection and anicteric hepatitis A, are not recognized as cases of viral hepatitis.[344,406] The frequency of symptoms with acute infection is influenced strongly by age. Children are less likely than adults to have symptomatic infection, and jaundice rarely occurs in children younger than 6 years of age.[151] In one report describing outbreaks in several day care centers, the proportion of infected children without symptoms was 84 percent in children younger than 3 years, 50 percent in children 3 to 4 years of age, and 20 percent in children 5 years or older.[159] Symptoms develop in most adults with acute infection. In a study of two outbreaks among young adult U.S. military personnel, symptoms developed in 76 to 97 percent of infected persons, and approximately 55 percent were icteric.[213]

Clinical Signs and Symptoms

In an individual patient, the clinical symptoms of acute hepatitis A are indistinguishable from those caused by other forms of viral hepatitis. Particularly in older children and adults, the onset of illness often is quite abrupt and may consist of fever, myalgia, anorexia, malaise, nausea, intermittent dull abdominal pain, and vomiting. Fever (temperature rarely higher than 38.9° C [102° F]) and headache occur more frequently than in other forms of acute viral hepatitis.[350] Pediatric patients may have diarrhea or, less commonly, upper respiratory tract symptoms such as cough, sore throat, and runny nose, and the diagnosis of hepatitis A might not be considered in children with predominantly respiratory or gastrointestinal symptoms and transient fever without the typical malaise, fatigue, and anorexia.[138,219] Dark urine followed by jaundice and light-colored stool, if present, will appear within a few days to a week after onset of the prodromal symptoms.[29,156,213,219] When this icteric phase begins, symptoms often resolve and appetite returns in young children, but older children and adult patients may experience a transient worsening in the prodromal symptoms of anorexia, malaise, and weakness.[199,260]

In addition to jaundice and scleral icterus, physical findings may include mild hepatomegaly and tenderness, but severe tenderness suggests other diagnoses. The spleen may be palpable in 10 to 20 percent of patients, and posterior cervical adenopathy may be present.[76,213,363] Pleural effusions have been reported to occur, do not appear to be associated with more severe disease, and resolve spontaneously.[4] Ascites, peripheral edema, and

findings indicative of hepatic encephalopathy suggest the presence of a more severe form of hepatitis (see the discussion on atypical clinical manifestations and complications of hepatitis A). Ultrasonographic findings in children with uncomplicated hepatitis A have included edema or thickening of the gallbladder wall, abdominal lymphadenopathy, and, less commonly, transient ascites and pancreatic abnormalities.[76,193]

The symptoms of hepatitis A last for several weeks on average and usually not longer than 2 months.[200] Prolonged or relapsing hepatitis A can occur (see the discussion on relapsing hepatitis A) and, in the case of prolonged hepatitis A, may be associated with genetic markers for autoimmune hepatitis.[127]

Laboratory Abnormalities

As in other forms of viral hepatitis, during HAV infection, inflammation of the liver is accompanied by abnormalities in serum hepatic enzymes, with increases in serum, aspartate aminotransferase (AST), alkaline phosphatase, and γ-glutamyltranspeptidase (GGTP) levels. Elevations of serum ALT and AST occur most consistently and may precede the appearance of symptoms by a week or more (see Fig. 167-2). Peak levels generally occur 3 to 10 days after the onset of symptoms and are between 200 and 5000 IU but can reach as high as 20,000 IU. The level of ALT usually is higher than that of AST because the inflammatory response is destructive, particularly to the plasma membrane, in acute viral hepatitis. ALT is found in the cytosol of the plasma membrane, whereas AST is located mainly in cell mitochondria.[156]

Serum bilirubin levels, although frequently elevated, usually remain below 10 mg/dL and peak 1 to 2 weeks after illness begins. Higher levels can be seen in some patients, especially when HAV infection is complicated by cholestasis (see the section on cholestatic hepatitis A) or hemolysis secondary to an underlying glucose-6-phosphate dehydrogenase (G6PD) deficiency state.[71] In patients with G6PD deficiency, indirect bilirubin may account for more than 50 percent of the total bilirubin. Alkaline phosphatase concentration and 5′-nucleotidase activity usually are elevated only mildly, rarely reaching more than 2 or 3 times the normal level. GGTP levels generally are 3 to 10 times the upper limit of normal.

Serum immunoglobulin levels often are elevated, and IgM levels frequently are higher than those in acute hepatitis B and non-A, non-B hepatitis.[411] In patients without underlying liver disease, the prothrombin time usually is normal. A prolonged prothrombin time, generally associated with severe liver damage, is a prognostic indicator for the development of fulminant hepatitis.[402]

Patients with acute HAV infection usually have a mild lymphocytosis with occasional atypical mononuclear cells.[260] Except for patients who have hemolysis associated with G6PD deficiency, the hematocrit generally is normal.[71,260]

Apart from patients who have relapsing or cholestatic hepatitis A (see the section on atypical clinical manifestations and complications of hepatitis A), serum bilirubin and aminotransferase levels usually return to normal by 2 to 3 months after the onset of illness in most patients.[200]

Diagnostic Tests

Because the pattern and magnitude of symptoms and the hepatic enzyme abnormalities of hepatitis A are not distinctive for hepatitis A, the diagnosis requires serologic detection of IgM anti-HAV along with demonstration of an acute onset of signs and symptoms of hepatitis and jaundice or elevated aminotransferase levels. Persons with signs and symptoms of hepatitis and an epidemiologic link to other confirmed cases are likely to have hepatitis A, even if no laboratory confirmation is available. Sensitive and specific radioimmunoassays or enzyme immunoassays show that virtually all patients have detectable IgM anti-HAV during the acute or early convalescent phase of HAV infection (see Fig. 167-2).[228] A small proportion (3%) of patients tested within 3 days of the onset of symptoms may be IgM anti-HAV negative but become IgM anti-HAV positive within the initial 2 weeks of illness.[228] During the first 4 to 8 weeks after the onset of symptoms, the titer of IgM anti-HAV in serum is high.[163] Antibody generally disappears within 6 months, although rarely it can be detected for 2 years or longer.[110,163,198,228]

False-positive IgM anti-HAV test results among persons who have no other evidence of recent infection have been reported, suggesting a low positive predictive value when it is used to test asymptomatic persons with no known recent HAV exposures.[62,65] IgM anti-HAV may be detectable for a longer time in patients with symptomatic illness than in those with asymptomatic infection.[163,185,340]

IgG anti-HAV is present in low titer at or shortly after the onset of acute HAV infection, and the titer rises during the course of several weeks as the IgM anti-HAV titer falls (see Fig. 167-2). IgG anti-HAV remains detectable in serum for the lifetime of the individual and confers lasting protection against disease. Secretory IgA antibodies are detected in a minority of humans or primates with acute HAV infection but are unlikely to provide any significant protection against HAV infection.[345] IgG anti-HAV is transferred passively across the placenta and declines to undetectable levels in most infants by the time they reach 12 to 15 months of age.[27,229,230]

Commercially available enzyme immunoassays either detect total (IgG and IgM) antibody against HAV capsid proteins by using a competitive inhibition (blocking) format or detect IgM antibody to capsid proteins by using an IgM capture format.[220] These assays do not measure the neutralizing antibodies responsible for biologic activity against HAV, but detection of total anti-HAV by conventional assays is correlated with the appearance of neutralizing antibodies.[202,220] Neutralizing antibody can be detected by assays that measure inhibition of HAV in cell culture (i.e., radioimmunofocus inhibition test or plaque assay).[11,88,220,222] Neutralizing antibodies elicited against one strain of HAV have been shown to have biologic activity against other HAV strains.[222]

When tested in parallel with a World Health Organization anti-HAV reference reagent, the lower limit of

detection of most commercially available assays is approximately 100 mIU/mL of anti-HAV.[147,220] Administration of immunoglobulin provides a high level of protection against hepatitis A, although the antibody concentrations achieved by passive immunization with immunoglobulin or active immunization with vaccine are 10- to 100-fold lower than those produced after natural infection.[220] Antibody concentrations achieved by passive or active immunization and known to provide protection against HAV infection both in vivo and in vitro may be below the level of detection of most commercial immunoassays.

The lower limit of antibody necessary to provide protection against HAV infection is unknown. In vitro studies with cell culture–derived virus suggest that low levels of antibody (e.g., <20 mIU/mL) are neutralizing.[222] Clinical trials that evaluated vaccine efficacy have not provided an estimate of the minimum protective antibody level because vaccine-induced levels of antibody have been very high and few infections have occurred in vaccinees. Experimental studies in chimpanzees indicate that very low levels of passively transferred antibody (<10 mIU/mL) obtained from immunized individuals do not protect against infection but prevent clinical hepatitis and shedding of virus.[297]

PCR assays can be used to detect HAV RNA in stools and sera of persons with HAV infection, although these tests are available only in a few research laboratories. PCR techniques using serum specimens have been useful in some clinical, epidemiologic, or environmental studies. Although HAV concentrations in stool decline quickly after illness onset, HAV RNA can be detected in most serum specimens that are collected within 4 to 6 weeks after onset of illness.[43]

ATYPICAL CLINICAL MANIFESTATIONS AND COMPLICATIONS OF HEPATITIS A

Table 167-1 lists the atypical clinical manifestations and complications of hepatitis A.

TABLE 167-1 **Atypical Clinical Manifestations and Complications of Hepatitis A Virus Infection**

Relapsing hepatitis A[152,317,361]
Fulminant hepatitis A[241,275,300,360]
Cholestatic hepatitis A[154,361]
Hepatitis A triggering autoimmune hepatitis[361,379]
Extrahepatic manifestations
Transient rash or arthralgias[150,361]
Papular acrodermatitis of childhood[312]
Cutaneous vasculitis[95,174,175]
Cryoglobulinemia[174,175,317]
Guillain-Barré acute syndrome[351]
Other neurologic syndromes (e.g., myeloradiculopathy, mononeuritis, vertigo, meningoencephalitis)[19,40,351]
Renal syndromes (acute renal failure, nephritic syndrome, acute glomerulonephritis)[17,100,183]
Pancreatitis[256]
Aplastic anemia and thrombocytopenia[124,234]

Relapsing Hepatitis A

Relapsing hepatitis is a relatively common manifestation of hepatitis A that occurs in approximately 10 percent of patients.[317] One to 4 months after having the initial episode of acute hepatitis, these patients have a second episode; more than one relapse rarely occurs.[152,317,361] Patients with relapsing hepatitis A have no distinctive clinical features of their first disease episode. After the first episode, most patients experience a significant improvement in symptoms and biochemical abnormalities. However, the frequency with which serum aminotransferase levels completely normalize during this period has been variable; in one report, normalization occurred in only one of seven patients with relapsing hepatitis A.[361] The relapse episode of hepatitis rarely is more severe than the initial episode and is accompanied by elevated serum aminotransferase levels (typically to >1000 U/L) and persistence of IgM anti-HAV. Molecular studies have demonstrated the presence of HAV in stool and HAV RNA in serum during relapse, but whether patients are infectious is unknown.[152] The illness usually lasts a total of 16 to 40 weeks and results in full recovery.[152,317] Although the pathogenesis of relapsing hepatitis is unknown, it probably is immunologically mediated.[317] Persistent HAV infection with a relapsing clinical course has been reported in patients after they have undergone liver transplantation for fulminant hepatitis A; HAV-specific genomic sequences have been identified in the grafts of these patients.[126,402]

The IgA has been postulated as a carrier supporting hepatotropic transport of HAV, which may contribute to different clinical outcomes.[115] Over a period of several weeks after infection, anti-HAV IgA is able to promote an enterohepatic cycling of HAV, resulting in continuous endogenous reinfection of the liver. A mouse model demonstrated that highly avid IgG antibodies, which are present in later times of the infection, can terminate the reinfection. The endogenous reinfections in the presence of a developing neutralizing immunity might contribute to prolonged, as well as relapsing, courses of HAV infections, and the IgA may act as a protracting factor.[115]

Fulminant Hepatitis A

In the United States, a relatively small proportion of all fulminant hepatitis is caused by hepatitis A.[241,279,300,318,360] A prospective multicenter study conducted among 348 children with acute liver failure in the United States, Canada, and the United Kingdom found that only three cases (1%) could be attributed to hepatitis A.[343] However, 26 to 60 percent of children with acute liver failure had hepatitis A in tertiary care center–based studies conducted in Turkey, India, Argentina, and Pakistan.[15,18,21,321] Among patients hospitalized with hepatitis A, the case-fatality rate has been estimated to be 0.14 percent.[250] In the 1988 Shanghai epidemic that involved primarily adolescents and young adults, 47 deaths (0.015%) were recorded among the 310,746 diagnosed cases.[79] Between 1998 and 2005, 29 adults with HAV IgM–positive acute liver failure were enrolled in the Acute Liver Failure Study Group (ALFSG) in the United States. Acute HAV

accounted for 3.1 percent of the patients enrolled. At 3 weeks follow-up, 16 had spontaneously recovered (55%), 9 underwent transplantation (31%), and 4 had died (14%). The proportion of HAV cases enrolled in the ALFSG significantly decreased from 5 to 0.8 percent between 1988 and 2005 (p <.007).[356]

On the basis of national surveillance data in the United States; death occurs in 0.3 to 0.6 percent of persons with symptomatic hepatitis A, reaching 1.8 percent among those over 50 years of age.[325] In 2008, the mortality rate of hepatitis A was 0.02/100,000 population (n = 83). During 2004 to 2008, the mortality rates were highest among persons older than 75 years in contrast to other age groups, and the overall mortality rate for that population was 0.12/100,000 population in 2008. From 2004 through 2008, the hepatitis A mortality rate was consistently higher among males than among females.[68]

Host factors reported to be associated with an increased risk for development of fulminant hepatitis include older age[45,208,250,385,405]* and underlying chronic liver disease.* Reported findings among persons with fulminant disease include nucleotide or amino acid substitutions in the 5′ untranslated region,[145] P2 region, and P3 region of the HAV genome.[265] Viral factors such as substitution rate in the entire genome were not associated with acute liver failure in the 29 patients identified with HAV liver failure in the adult ALFSG from 1998 to 2004; however, a negative PCR (undetectable or very low viral load) was the single factor that correlated more significantly with more severity and worse outcomes.[2] This finding has been previously described in the literature and suggests that the excessive host response maybe a determining factor in the development of fulminant hepatitis A.[304] An in depth analysis conducted in India for a 5-year period concluded that higher CD8 T cells and coinfection with other viral hepatitis infections were more commonly associated with fulminant hepatitis and contrary to previous findings; higher viral load was also an important contributing factor.[170]

Fulminant hepatitis A has no distinctive clinical features that distinguish it from fulminant hepatic failure of other causes. Within approximately 8 weeks of the onset of illness, symptoms of hepatic encephalopathy and marked prolongation of prothrombin time are noted in patients with no history of previous liver disease.[276] Complications can include cerebral edema, sepsis, gastrointestinal bleeding, and hypoglycemia. The prognosis of fulminant hepatitis A without transplantation is better than that of fulminant disease related to other viral causes, and 40 to 70 percent of patients can be expected to recover.[150,275,318,360] In one hospital series, more rapid onset to liver failure after onset of jaundice was associated with improved outcome, and higher bilirubin concentration and more prolonged prothrombin time were associated with poor outcomes.[99]

Extrahepatic Manifestations

During acute hepatitis A, transient rash and arthralgias occur in as many as 14 and 19 percent of patients, respectively, particularly during the prodromal period.[150,361] Urticaria has been reported but occurs less frequently than in acute hepatitis B.[109] Papular acrodermatitis of childhood, the Gianotti-Crosti syndrome, rarely occurs in the United States but has been reported elsewhere in association with HAV infection.[312] The cutaneous lesions, which consist of nonpruritic, symmetric flat papules on the face, extremities, and buttocks, may persist for several weeks before spontaneously resolving.[116]

Other extrahepatic manifestations that occur chiefly in association with cholestatic or relapsing hepatitis A include cutaneous vasculitis and cryoglobulinemia.[95,174,175] The vasculitis, manifested as erythematous maculopapular lesions often affecting the lower extremities and buttocks and typically associated with purpura, appears as leukocytoclastic vasculitis and granular deposits of IgM anti-HAV and complement in blood vessel walls in skin biopsy specimens. Cryoglobulinemia includes cryoglobulins composed of IgG and IgM and IgM anti-HAV antibodies.[95,174,175,317] These manifestations resolve spontaneously with resolution of the hepatitis.

In the absence of fulminant disease, neurologic syndromes have been observed only rarely in association with hepatitis A. Guillain-Barré syndrome has been reported to occur 3 days to 2 weeks after the onset of hepatitis A, as have myeloradiculopathy, vertigo, mononeuritis (cranial or peripheral nerve), meningoencephalitis, and exacerbation of multiple sclerosis.[19,40,286,351] Renal complications, including acute renal failure, nephrotic syndrome, and acute glomerulonephritis, also rarely have been reported in children who did not have fulminant disease.[17,100,183] Self-limited, mild pancreatitis likewise appears to occur.[256] Reported hematologic complications include aplastic anemia and severe thrombocytopenia.[124,234] Gestational complications, including premature rupture of membranes and placental separation, have been reported among pregnant women with acute hepatitis A, but infants born to these women were healthy otherwise.[118,311]

Cholestatic Hepatitis A

Cholestatic hepatitis occurs in a small percentage of patients with hepatitis A. These patients are deeply icteric and may have pruritus, fatigue, fever, loose stools, anorexia, dark urine, and weight loss. In two reports of 10 patients with cholestatic hepatitis A, peak serum bilirubin levels generally were higher than 10 mg/dL, with some as high as 38 mg/dL, and remained elevated for 12 to 16 weeks.[154,361] Serum aminotransferase levels declined but remained elevated during the period of cholestasis. In one of these reports, five patients had prolonged prothrombin times that normalized with the administration of vitamin K.[154]

Cholestatic hepatitis A can be distinguished from obstructive jaundice by normal abdominal ultrasound findings. Conducting further invasive diagnostic procedures, such as liver biopsy or direct forms of cholangiography, is not necessary in most cases.[317] Although patients will recover completely without therapy, a course of corticosteroids with a gradual taper during a span of at least

*References 3, 96, 189, 223, 380, 385, 403, 405.

4 weeks has been reported to hasten relief of symptoms and resolution of cholestasis.[207,317,408]

Hepatitis A Triggering Autoimmune Hepatitis

Several reports have described patients in whom hepatitis A is followed by type 1 autoimmune chronic hepatitis.[299,361,379] Laboratory studies demonstrated a T-cell defect in these patients, suggesting a genetic predisposition to the development of autoimmune hepatitis that is "triggered" by HAV infection. These patients have required corticosteroid therapy, sometimes for long periods.

TREATMENT

Hepatitis A has no specific therapy, and because HAV infection is self-limited and does not result in chronic infection or chronic liver disease, treatment generally is supportive. Hospitalization may be necessary for patients who are dehydrated from nausea and vomiting or who have fulminant hepatic failure. Because no conclusive data indicate that bed rest or inactivity influences the course of illness, no restriction of activity is necessary. Similarly, no specific diet is indicated, although many patients may have an intolerance to fatty foods during their illness. Medications, particularly those that have the potential to cause hepatic damage and those that are metabolized by the liver, including acetaminophen, should be used with caution. The half-life of these medications may be prolonged.

A specific therapy for fulminant hepatic failure caused by hepatitis A has not been established. Small uncontrolled trials conducted among adults in the 1980s suggested that some patients benefited from prostaglandin E or IFN, but no additional data to indicate that these therapies are efficacious have been published. No evidence exists that exchange transfusions, plasmapheresis, or corticosteroids are effective.[125,156] Adults with fulminant hepatitis A who received prostaglandin E or IFN have been reported to show improvement in small, uncontrolled trials.[227,335] Amantadine and ribavirin have shown activity in vitro against HAV.[86] Liver transplantation is successful in some patients.[164,334,360,384] Persistent HAV infection has been demonstrated in some transplant recipients, but whether it affects survival is unknown.[117,126] One case report from Korea described an adult patient with recurrent hepatitis A with liver failure after a successful transplantation; which prompted a second liver transplant with later evidence of hepatitis A ongoing infection.[282] Because survival rates of adult and pediatric patients are relatively high without transplantation and no single factor is predictive of a poor outcome, establishment of criteria for choosing candidates for transplantation has been difficult.[150,276,360,377] Reported survival rates after transplantation in patients with fulminant hepatitis from all viral causes range from 40 to 89 percent, depending on the severity of liver failure and other factors.[214,360]

PREVENTION

In addition to general measures of good personal hygiene, particularly handwashing; provision of safe drinking water; and proper disposal of sanitary waste, preexposure or postexposure immunization primarily with hepatitis A vaccine or with immunoglobulin can prevent the acquisition of hepatitis A.

Immunoglobulin

Immunoglobulin is a sterile solution of antibodies prepared by a serial cold ethanol precipitation procedure from pooled human plasma that has tested negative for hepatitis B surface antigen, antibody to human immunodeficiency virus (HIV), and antibody to hepatitis C virus.[78] This precipitation procedure has been shown to inactivate hepatitis B virus and HIV.[52] Since 1995, immunoglobulin prepared in the United States has been required to be negative for hepatitis C virus RNA by PCR amplification or to be produced by a method that ensures additional virus inactivation. When it is administered before exposure or within 2 weeks after exposure, immunoglobulin is more than 85 percent effective in preventing hepatitis A by passive transfer of anti-HAV.[198,258,347] Whether immunoglobulin completely prevents infection or leads to asymptomatic infection and the development of persistent anti-HAV (passive-active immunity) probably is related to the amount of time that has elapsed between exposure and administration of immunoglobulin.[219,347] Although in recent years immunoglobulin lots have had slightly lower titers of anti-HAV, probably because of a decreasing prevalence of previous HAV infection in plasma donors, no clinical or epidemiologic evidence of decreased efficacy has been reported.[354]

Immunoglobulin may be given to persons who are traveling to countries with high, transitional, or intermediate endemicity of HAV infection (see Fig. 167-3) instead of or in addition to hepatitis A vaccine.[65] Immunoglobulin should be given to children younger than 12 months who are traveling to such countries because hepatitis A vaccine is not licensed in the United States for children in this age group (see the section on vaccines).[65] Although hepatitis A often is asymptomatic in infants and young children, preexposure prophylaxis is indicated to prevent the rare severe cases and transmission to others after return from abroad.

For preexposure prophylaxis of travelers, the dose of immunoglobulin is 0.02 mL/kg body weight if travel will be for less than 3 months. Because of the decay of passive immunity during the course of time, a dose of 0.06 mL/kg is necessary for persons who will be abroad for 3 to 5 months, and readministration every 5 months is necessary for extended trips. Hepatitis A vaccine, if it is not contraindicated, is a better choice for such persons.

Aggressive use of immunoglobulin or vaccine is indicated to control hepatitis A outbreaks in child care centers in which hepatitis A is diagnosed in a child or employee[65,64,324] and in other settings (e.g., hospitals and facilities for developmentally disabled persons) when outbreaks occur.[58] When a food handler is identified with

hepatitis A, postexposure prophylaxis should be administered to other food handlers at the establishment and under limited circumstances to patrons.[51,65,135] Once cases are identified that are associated with a food service establishment, it generally is too late to administer postexposure prophylaxis to patrons because the 2-week postexposure period during which prophylaxis is effective will have passed.

Previously unvaccinated household or sexual contact of patients with hepatitis A should receive postexposure prophylaxis. In the absence of postexposure prophylaxis, secondary attack rates of 15 to 30 percent have been reported in households, with higher rates of transmission occurring from infected young children than from infected adolescents and adults. Attack rates in food handlers are generally lower.[197]

Immunoglobulin is usually used for postexposure prophylaxis in susceptible persons who are either children younger than 12 months or persons older than 40 years of age, immunocompromised persons, and persons with chronic liver disease.[197]

For postexposure prophylaxis, 0.02 mL/kg body weight of immunoglobulin is administered intramuscularly. For infants and young children, the injection can be administered in the anterolateral aspect of the thigh or the deltoid muscles; for older children and adolescents, the injection should be administered in the deltoid or gluteus muscles, into which a large volume of immunoglobulin can be injected.[59] If the immunoglobulin is administered in the gluteus, the injection should be given in the superolateral aspect to avoid injury to the sciatic nerve.[59]

Vaccine is recommended as postexposure prophylaxis in healthy persons 12 months through 40 years of age as of 2007 because it induces active immunity providing longer protection, has higher acceptability and availability, and is easy to administer.[65,69,197]

Immunoglobulin does not interfere with the immune response to oral poliovirus vaccine, to yellow fever vaccine, or, in general, to inactivated vaccines. However, immunoglobulin can interfere with the immune response to some live attenuated vaccines (e.g., measles-mumps-rubella vaccine [MMR] and varicella vaccine). Administration of MMR and varicella vaccines should be delayed for at least 3 months and at least 5 months, respectively, after the administration of immunoglobulin. Immunoglobulin should not be given within 2 weeks after the administration of MMR or within 3 weeks of the administration of varicella vaccine, unless the benefits of immunoglobulin administration are greater than the benefits of vaccination.[59] For travelers younger than 1 year of age in whom the use of immunoglobulin may interfere with the administration of other needed vaccines (e.g., MMR and varicella), the use of inactivated hepatitis A vaccine could be considered (see the discussion on inactivated vaccines).

Serious adverse events from immunoglobulin rarely occur. Because anaphylaxis has been reported after repeated administration to persons with IgA deficiency, these persons should not receive immunoglobulin.[119] Pregnancy or lactation is not a contraindication to the administration of immunoglobulin. For infants and pregnant women, a preparation that does not include thimerosal is preferable.

TABLE 167-2 Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines Available in the United States

Age (yr)	Vaccine*	Dose	Volume (mL)	No. of Doses	Schedule† (mo)
1-18	HAVRIX	720 ELU	0.5	2	0, 6-12
	VAQTA	25 U	0.5	2	0, 6-18
≥19	HAVRIX	1440 ELU	1.0	2	0, 6-12

>18	TWINRIX	720 ELU	1.0	3	0, 1, 6‡

From Center for Disease Control and Prevention. Prevention of hepatitis A through active or passive immunization: recommendation from the advisory Committee on Immunization Practices (ACIP). *MMWR Morb Mortal Wkly Rep* 2006;**55**(RR-7):1-23.

*HAVRIX is manufactured from HAV strain HM175 by GlaxoSmithKline; VAQTA is manufactured from HAV strain CR326F′ by Merck & Co, Inc.; TWINRIX is a combined hepatitis A and hepatitis B vaccine that also contains 20 µg per dose recombinant hepatitis B surface antigen protein.

†Zero months indicates initial dose; subsequent numbers represent months after the initial dose.

‡An alternative four-dose schedule, given on days 0, 7, 21-30, followed by a dose at month 12, also is licensed in the United States.

ELU, Enzyme-linked immunosorbent assay units.

Hepatitis A Vaccine

The ability to propagate HAV in cell culture allowed the development of hepatitis A vaccines. Both inactivated and live attenuated hepatitis A vaccines have been developed by use of defined isolates from infected cell lines.*

However, only inactivated vaccines have been evaluated for efficacy in controlled clinical trials and licensed in the United States, and the live attenuated vaccines evaluated to date do not appear to offer any distinct advantage over inactivated vaccines.[176,392] Available data indicate that both inactivated and live attenuated hepatitis vaccine are capable of providing long-term protection.[280]

Vaccine Preparation and Performance

Inactivated hepatitis A vaccines are prepared by a method similar to that used to prepare inactivated poliovirus vaccine, by propagation of cell culture–adapted virus in human fibroblasts, purification by ultrafiltration or other methods, formalin inactivation, and adsorption to an aluminum hydroxide adjuvant.[14,75] Inactivated vaccines using the HM175 strain and the CR326F′ strain have been licensed in pediatric and adult formulations for intramuscular administration and are available in the United States for persons 12 months of age and older (Table 167-2). One of these vaccines (HM175 strain) is formulated with 2-phenoxyethanol as a preservative, whereas

*References 90, 237, 238, 253, 296, 336.

the other is formulated without a preservative (see Table 167-2).[284] The antigen content of one vaccine (CR326F′ strain) is expressed as units of HAV antigen as defined by a standard; the antigen content of the other vaccine (HM175 strain) is determined by reactivity in a quantitative immunoassay for HAV antigen and is expressed as enzyme-linked immunosorbent assay units (ELU; see Table 167-2).

Two other inactivated hepatitis A vaccines are manufactured and available in Europe and other parts of the world.[175,211,287,383] In addition, a combination inactivated hepatitis A and recombinant hepatitis B vaccine is available in the United States for persons 18 years and older[64] and a pediatric formulation is available in Europe, Canada, and other parts of the world.[106]

In extensive studies in children and adults, the inactivated hepatitis A vaccines available in the United States have been found to be highly immunogenic. In general, after one dose of vaccine, 95 to 100 percent of children 1 year or older and adults respond with concentrations of antibody considered to be protective; a second dose given 6 to 18 months later results in a boost in antibody concentration and probably is important for long-term protection.* Persons whose second dose is delayed as long as 3 to 8 years after the first dose have responses to vaccination similar to the responses of those who receive the vaccine on licensed schedules.[24,179,400] Studies conducted among infants and children younger than 18 months have demonstrated that simultaneous administration of hepatitis A vaccine with diphtheria–tetanus–acellular pertussis (DTaP), *Haemophilus influenzae* type b, hepatitis B, MMR, and inactivated poliovirus vaccines does not affect the immunogenicity and reactogenicity of these vaccines.[27,35,92,252,370] IgM anti-HAV occasionally can be detected by standard assays, primarily if it is measured soon (i.e., 2 to 3 weeks) after vaccination.[332,381]

Conditions that may result in reduced immunogenicity include HIV infection, chronic liver disease, and older age. Among adults with HIV infection, 61 to 87 percent had protective antibody concentrations after completing the vaccination series.[166,191,269,387] Higher $CD4^+$ T-lymphocyte count at baseline was associated with response to vaccination.[13,166,191,305,387] However, HIV-infected persons with normal or near-normal $CD4^+$ T-lymphocyte counts have response rates that exceed 95 percent.[390] A retrospective study in adult patients with HIV who received two doses of HAV vaccine demonstrated a durable seropositive response for up to 6 to 10 years after HAV vaccination. Suppressed HIV RNA levels were associated with durable HAV responses.[89] Awareness of hepatitis susceptibility and hepatitis coinfection status in HIV-infected patients is essential for optimal clinical management. Despite recommendations for hepatitis screening and vaccination of HIV-infected MSM, rates for screening and vaccination remained suboptimal in the United States from 2004 to 2007.[168] HIV-infected patients have an elevated risk for HAV coinfection, which is significant considering the elevated prevalence of liver disease in this population. Furthermore, HIV-infected persons may experience prolonged HAV viremia, which has important public health implications for transmission within the community.[89] Among persons with chronic liver disease, seroprotection rates were similar to those observed among healthy adults, but the final antibody concentrations were substantially lower.[190,217]

Studies in children younger than 1 year of age indicate that the vaccine is safe and immunogenic for those who do not have passively transferred antibody from previous maternal HAV infection.[27,226,291,366] In studies of infants who received hepatitis A vaccine according to several different schedules, those with passively transferred maternal antibody at the time of vaccination responded, but final antibody concentrations were approximately one-third to one-tenth those of infants who did not have passively transferred antibody and were vaccinated according to the same schedule.* The clinical significance, if any, of these lower antibody concentrations is unknown. One study found that all infants vaccinated in the presence of passively transferred maternal antibody responded to a booster dose given 6 months later with an anamnestic response, suggesting that they had been primed by the primary series.[93] However, in another small study, two of six children who had lost detectable antibody did not have an anamnestic response to a booster dose administered approximately 6 years after they had received the primary vaccine series in infancy in the presence of passively transferred antibody.[136] Most infants born to anti-HAV–positive mothers have lost detectable antibody by the time they reach 12 to 15 months of age, and both pediatric hepatitis A vaccines are now licensed for use in children as young as 12 months.[141,230]

Inactivated hepatitis A vaccine has been shown to be highly efficacious in preventing clinically apparent disease. In a study of approximately 40,000 Thai children 1 to 16 years of age, the efficacy of inactivated vaccine (HM175 strain) was 94 percent (95% CI, 79%, 99%) after two doses (360 ELU per dose) administered 1 month apart.[176] In a study of another inactivated vaccine (CR326F strain) involving approximately 1000 children 2 to 16 years of age in a New York community with high hepatitis A rates, efficacy was 100 percent (lower bound of the 95% CI, 87%) starting 17 days after the administration of one dose (25 U).[392]

Since hepatitis A vaccines became available in the United States in 1995, studies, demonstration projects, and surveillance data have evaluated their effectiveness in controlling and preventing the development of hepatitis A in communities. In areas with the highest hepatitis A rates, such as Native American and Alaska Native communities, vaccination of the majority of children—and in some cases adolescents and young adults—resulted in a rapid decline in the incidence of disease, and with ongoing routine vaccination of children, the reduction in incidence of disease has been sustained.[33,55,248] In larger, more heterogeneous communities with lower but consistently elevated hepatitis A rates, interruption of ongoing

*References 20, 27, 75, 169, 249, 266.

*References 27, 93, 226, 229, 291, 366.

community-wide epidemics by vaccination of children proved more difficult.[85] In contrast, sustained routine vaccination of children can reduce hepatitis A incidence markedly during the course of time (see discussion on vaccine recommendations and use).[16,92,111]

Hepatitis A vaccine also is effective when it is used to prevent infection after exposure. Hepatitis A vaccine administered soon after exposure prevented infection in a chimpanzee model.[307] Hepatitis A vaccine was found to be 79 percent efficacious in preventing infection in contrast to no treatment in a small randomized trial conducted in Italy.[313] However, the confidence interval was wide (7% to 95%), and the study did not include a comparison group that received passive postexposure prophylaxis with immunoglobulin.[26] In a randomized, controlled trial conducted in Kazakhstan, among persons aged 2 to 40 years who were contacts of hepatitis A cases, the efficacy of hepatitis A vaccine administered within 14 days after exposure to HAV was shown to be similar to that of immunoglobulin in healthy children and adults younger than 40 years of age.[381] Based on their results and because the vaccine offers advantages over immunoglobulin, the Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service currently recommends the hepatitis A vaccine in preference to immunoglobulin for postexposure prophylaxis of healthy persons from the ages of 12 months to 40 years.[65] Advisory groups or expert panels in some other countries also have recommended that hepatitis A vaccine be used as the primary means of preventing hepatitis A after exposure.[268,352]

Experience to date indicates that the incidence of adverse events after vaccination is comparable to that after the administration of other widely used vaccines. In prelicensure clinical studies in children, the side effects reported most frequently included soreness, tenderness, warmth, or induration at the injection site (4% to 19%); feeding problems (8%); and headache (4%).[35,64,252] Through 2005, more than 188 million doses have been sold worldwide, including more than 50 million doses in the United States.[64] No serious adverse events in children or adults have been identified that could be definitively ascribed to hepatitis A vaccine.[36,64] The Vaccine Adverse Events Reporting System (maintained by the U.S. Food and Drug Administration and the CDC) has received approximately 6000 reports of adverse events occurring after receipt of hepatitis A vaccine. The most common events were minor and of brief duration, such as fever, injection-site reactions, rash, and headache. The 871 serious adverse events included Guillain-Barré syndrome, transaminitis, idiopathic thrombocytopenic purpura, and seizures among children.[64,271] Rare adverse events reported after marketing include syncope, jaundice, erythema multiforme, anaphylaxis, brachial plexus neuropathy, transverse myelitis, encephalopathy, and others. For events for which incidence rates are available, such as Guillain-Barré syndrome, reported rates were not higher than reported background rates.[64]

Anti-HAV persists at protective levels in vaccinated adults for at least 10 to 12 years after vaccination,[372,376,375] and more recent publications have demonstrated protective levels up to 15 and 17 years after vaccination[373,374] and in children for at least 5 to 10 years after vaccination.[128,161,372] Available data indicate that both inactivated and live attenuated hepatitis A vaccine are capable of providing long-term protection for up to 15 years in both children and adults.[280]

In one follow-up study, two thirds of infants who did not have passively transferred maternal antibody at the time of vaccination had detectable anti-HAV 6 years later, and all who had lost antibody had an anamnestic response to a booster dose.[136] Estimates based on kinetic models of decline in antibody suggest that the duration of protection could be 15 to 25 years or longer.[372,398,399] A study randomized by maternal anti-HAV status included 197 children younger than 2 years of age who received different schedules of HAV vaccine and demonstrated that the seropositivity induced by hepatitis A vaccine can persists for at least 10 years regardless of presence of maternal anti-HAV.[326]

In some settings, performing prevaccination serologic testing may be considered in an attempt to reduce cost by not vaccinating persons with previous immunity.[48] Testing of children is not indicated because of their expected low prevalence of infection and the lower cost of vaccine for this age group. Testing may be considered for older adolescents and adults in certain population groups with a high prevalence of infection (e.g., Native Americans and Alaska Natives), persons who either were born in or lived for extensive periods in geographic areas that have high endemicity of HAV infection (e.g., Central and South America, Africa, and Asia), and adults 40 years of age and older, but the cost of testing, the vaccine cost, and the likelihood that the person will return for vaccination should be taken into account. Postvaccination testing is not indicated because of the high rate of response to the vaccine. Furthermore, most anti-HAV testing methods licensed for use in the United States cannot reliably detect the low anti-HAV concentrations generated by immunization.[69]

Vaccine Recommendations and Use

Recommendations for the use of hepatitis A vaccine were issued first by the ACIP (Table 167-3), the American Academy of Pediatrics, and other groups in 1996 and updated in 1999 and 2006.[8,54,58,64] As part of an incremental strategy aimed at achieving widespread routine vaccination, the 1999 recommendations called for routine vaccination of children living in areas where rates of hepatitis A consistently had been elevated (see Table 167-3). Various vaccination strategies that were suggested included vaccinating one or more single-age cohorts of children or adolescents, vaccinating children in selected settings (e.g., day care), and vaccinating children and adolescents over a wide range of ages in a variety of settings, such as when they seek health care for other purposes. The final step in this incremental strategy, routine vaccination of children older than 12 months nationwide, was recommended by the ACIP in 2006.[64]

The impact of routine vaccination of children initially was shown in areas that historically have had the highest hepatitis A rates (e.g., Native American communities), where this strategy had been recommended since 1996.

TABLE 167-3 Advisory Committee on Immunization Practices Recommendations for Routine Preexposure Use of Hepatitis A Vaccine

Group	Comments
All children at age 12-23 months*	Integrate into routine childhood vaccination schedule; children who are not vaccinated by age 2 years can be vaccinated at subsequent visits
Children aged 2-18 years	Maintain existing program†; can be considered in areas without existing programs
International travelers	Except persons traveling to Canada, Western Europe, Japan, Australia, or New Zealand, who are at no greater risk than in the United States
Men who have sex with men	Includes adolescents
Illicit drug users	Includes adolescents
Persons with chronic liver disease	Increased risk of fulminant hepatitis A with HAV infection
Persons receiving clotting factor concentrates	
Persons who work with HAV in research settings	
Anyone wishing to obtain immunity	

From Centers for Disease Control and Prevention: Prevention of hepatitis A through active or passive immunization. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2006;**55**(RR-7):1-23.

*Hepatitis A vaccine is not licensed for children younger than 12 months.

†States covered by 1999 ACIP recommendations (Alabama, Alaska, Arizona, California, Colorado, Idaho, Minnesota, Missouri, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Texas, Utah, Washington, Wyoming, and selected areas in other states).[58]

HAV, Hepatitis A virus.

Surveys conducted in 1999 to 2000 indicated vaccination coverage of 50 to 80 percent of preschool- and school-age Native American and Alaska Native children, thus suggesting that the recommendation for routine vaccination was being implemented.[33] By 2000, the incidence of hepatitis A in Native Americans and Alaska Natives had declined by 97 percent in contrast to the beginning of the preceding decade and was the same as the overall U.S. rate.[33]

National surveillance data indicate that routine vaccination of children living in areas with consistently elevated rates, which was recommended in 1999, has had an impact on the overall incidence of hepatitis A in the United States. Rates declined most dramatically among children in parts of the country where routine vaccination of children was recommended and where the estimated coverage was highest.[388]

Since 2001, incidence rates in each successive year have been historic lows, with the 2010 rate of 0.54 cases/100,000 population demonstrating a 94 percent decline in contrast to previous lows observed in the early 1990s.[70]

Vaccine coverage data are limited but indicate that declines in incidence have occurred with modest levels of coverage, suggesting a strong herd immunity effect.[9,93,314] Modeling studies suggested that 39 percent of potential cases were averted in 2001 because of the direct effects of immunization and herd immunity.[314] Similar observations have been made in Israel and Spain. The incidence of hepatitis A declined by 95 percent in Israel within 3 years after initiation of an immunization program among children 18 to 24 months old, even though no catch-up vaccination of other age groups was attempted.[93] Routine vaccination of 12-year-old children in Catalonia, Spain was followed by a 58 percent reduction in overall incidence.[111] Hepatitis A incidence is cyclic, and data from additional years are needed to verify that low rates are sustained and attributable to vaccination and to provide a definitive determination of the overall impact of this strategy of routine childhood vaccination. However, the consistency and strength of these data render alternative explanations unlikely.

The data indicating that vaccination of children could have a powerful impact on incidence rates in all ages and the demonstration of vaccine safety and immunogenicity for children as young as 1 year were key factors supporting the decision to expand routine vaccination to all children aged 12 to 23 months in the United States. Economic analyses also were considered. One study estimated that routine vaccination given when children reached 1 year of age in the United States would result in 183,806 fewer infections and 32 fewer deaths in a single U.S. birth cohort, with a cost-effectiveness ratio of $173,000 per life year gained and $24,000 per quality-adjusted life year gained.[302]

Vaccination of successive cohorts of children eventually should result in a sustained reduction in the incidence of disease nationwide and thus provide the opportunity to eliminate HAV transmission. To achieve this goal, implementation of recent ACIP recommendations for vaccination of young children nationwide will be needed. Pediatric combination vaccines that include hepatitis A vaccine would facilitate this effort.

Vaccination of persons at increased risk for acquiring hepatitis A, including travelers to countries where hepatitis A is endemic, adolescent and adult MSM, persons who use illegal drugs, those who work with HAV in research settings, and persons who have clotting factor disorders, also is recommended.[64] Persons with chronic liver disease who acquire hepatitis A have been reported to have a high case-fatality rate and are recommended for vaccination also.[64]

In 2009, ACIP recommended hepatitis A vaccination for all previously unvaccinated persons who anticipate close personal contact (e.g., household contact or regular babysitting) with an international adoptee from a country of high or intermediate endemicity during the first 60 days after arrival of the adoptee in the United States. The first dose of the two-dose hepatitis A vaccine series should

be administered as soon as adoption is planned, ideally within 2 weeks before the arrival of the adoptee.[66]

ACIP considered the likelihood that a child adopted by parents in the United States may be actively infected with hepatitis A and shedding virus at the time of the adoption. During 1998 to 2008, approximately 18.000 children were adopted from foreign countries by families in the United States each year. Of these, 99.8 percent came from countries where hepatitis A is considered of high or intermediate endemicity and approximately 85 percent were younger than 5 years of age.

ACIP also considered reports of HAV infection among persons in close contact with new adoptees from countries of high or intermediate endemicity. In 2007, the CDC was notified of a case of fulminant hepatitis A in a nontraveling household contact of an asymptomatic Ethiopian adoptee confirmed to have acute hepatitis A (IGM HAV positive). This case prompted an investigation that led to an identification of 20 additional cases of acute hepatitis A among persons who had close contact with newly arriving international adopted children and no history of traveling abroad.[137,285] HAV infection in international adoptees and their contacts between 2007 and 2009 was also reported in Minnesota.[348]

HAV infection during pregnancy may be associated with the risk for gestational complications. HAV serology and vaccination for pregnant women should be considered a high-prevalence area of acute hepatitis A.[311]

Hepatitis A is not routinely recommended for health care personnel, persons attending or working in child care centers, or persons who work in liquid or solid waste management (e.g., sewer workers or plumbers). ACIP does not recommend routine hepatitis A vaccination for food service workers, but vaccination may be considered on local epidemiology.[69]

RNA VIRUSES

SUBSECTION 2 *CALICIVIRIDAE*

CHAPTER 168

CALICIVIRUSES

Yalda C. Lucero • Miguel L. O'Ryan • David O. Matson

Caliciviridae is a family that currently includes five genera that differ in genomic organization and phylogenetic comparisons of genomic sequence identity, named *Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*, and *Nebovirus*.[38,69]

The first calicivirus-associated disease in animals was described in animals in 1932, when outbreaks of a vesicular exanthema restricted to domestic pigs occurred in California and spread through the United States (vesicular exanthema of swine virus [VESV] infection, prototype of the *Vesivirus* genus).[11] Although diagnostic tools were not available to identify the causative agent, epidemiologic observations suggested an infective origin that was transmitted probably through contaminated food. Extensive programs of sterilization of feed and restriction of feed types finally stopped the outbreaks in the 1950s. In the 1970s, VESV strains were first

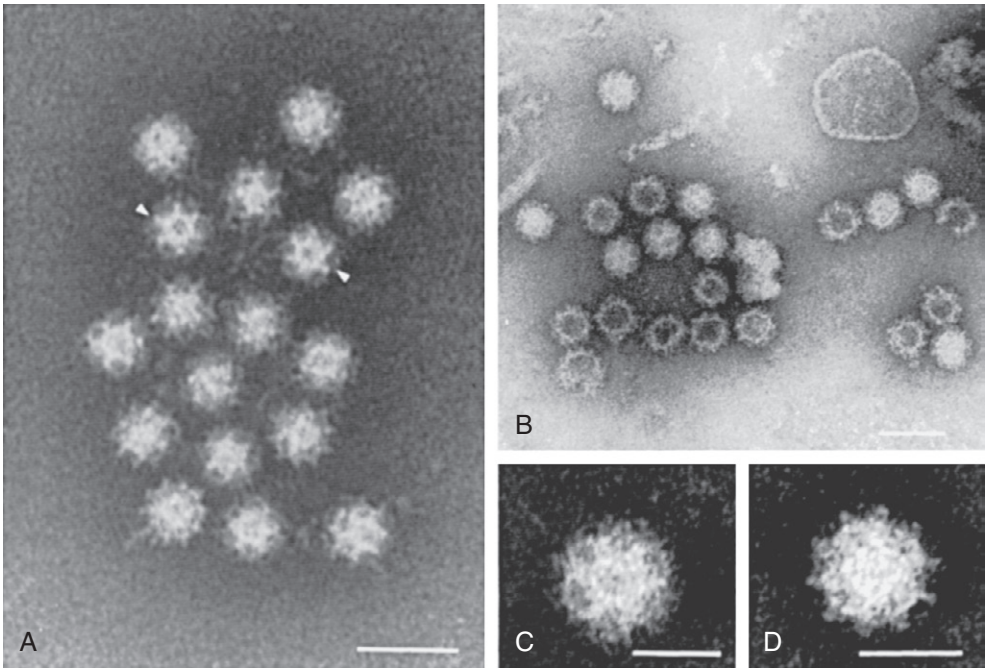

FIGURE 168-1 ■ Human calicivirus particles visualized by electron microscopy. Particles in a preparation of a purified Sapporo/1982/Japan prototype strain show distinct surface cups, and the Star of David pattern is visible on some particles (**a,** *arrowheads*). Particle staining, particle type, and debris in clinical specimens are variable, which frustrates the recognition of distinct structural features. **b,** Specimen from a child from Houston, Texas, infected with an antigenically distinct *Sapovirus.* Two particles at high magnification show the Star of David pattern (**c**) and the 10 surface projections (**d**) characteristic of calicivirus (specimen from a symptomatic child attending a daycare center in Phoenix, Arizona). Bar in **a** and **b** = 50 nm; bar in **c** and **d** = 25 nm.

visualized by electron microscopy; they had distinctive and unique features that led to the name *calicivirus* (from "chalice," for the virion's surface cups).[140]

Caliciviruses in humans were recognized first in 1972, when viral particles were isolated from stool samples of gastroenteritis patients involved in an outbreak, affecting schoolchildren, teachers, and their household contacts in Norwalk, Ohio.[1,101] Volunteer challenge studies proved the causal role of these round and rough-surfaced particles visualized by immune electron microscopy, which were named the Norwalk agent (prototype of the *Norovirus* genus). Many similar small, round-structured viruses (SRSVs) were described subsequently from outbreaks of gastroenteritis around the world. In parallel, investigators using electron microscopy to survey stool specimens from children with sporadic gastroenteritis visualized particles that did not have the appearance of SRSVs but instead were similar to the animal caliciviruses previously identified.[3,129,131] These "typical" caliciviruses occurred in a small percentage of sporadic diarrhea stool specimens and in a few outbreaks of gastroenteritis, including an outbreak in an orphanage in Sapporo, Japan (prototype of the *Sapovirus* genus). Biochemical and genomic sequencing analysis confirmed subsequently that the SRSVs (noroviruses) and human viruses with typical calicivirus morphologic features (sapoviruses) both belong to the *Caliciviridae*.[69,92]

In 1984, a highly fatal, highly contagious hepatitis was observed in European rabbits bred in China.[209] This syndrome spread some 7000 miles across Asia into Europe and reached Spain within 4 years, a dispersal rate of approximately 5 miles (8 kilometers) per day in a sedentary host. European rabbit populations experienced mortality rates exceeding 90 percent within 3 days of exposure. Typical calicivirus particles were visualized in infected rabbit livers, hence the rabbit hemorrhagic disease virus (RHDV; prototype of the *Lagovirus* genus).[146,156]

More recently, calicivirus isolates associated to gastroenteritis in bovines were recognized as a new genus, *Nebovirus.*[82,89,103]

These summaries illustrate the diversity of the ecologic relationships and the broad spectrum of illness (from mild gastroenteritis to fatal hepatitis) associated with members of the *Caliciviridae*. Next, we will discuss the structural, genetic, pathogenic, epidemiologic, and clinical features of caliciviruses, with emphasis on human infection.

PROPERTIES OF CALICIVIRUSES

Structural Features of the Virion

The *Caliciviridae* are a family of nonenveloped, icosahedral viruses with a positive-sense, polyadenylated, single-stranded RNA genome of approximately 7500 nucleotides in length. Cryoelectron microscopy and x-ray crystallography have resolved the three-dimensional structure of representative members of four of the five genera.[14,34,86,160] Typical calicivirus virion particles are 40 nm in diameter and have a T = 3 icosahedral symmetry, conformed by 90 dimers of the main structural protein, VP1 (Fig. 168-1).[160] VP1, is a 60-kDa protein that has two

TABLE 168-1 **Genera of Human and Animal Caliciviruses**

Genus	Known Hosts	Examples
*Norovirus**	Human, bovine, pig	Norwalk, Snow Mountain and Lordsdale viruses; Jena virus (bovine)
*Sapovirus**	Human, pig	Sapporo caliciviruses 82/Japan, 86/Houston, 90/Houston; Manchester and Plymouth viruses; porcine enteric calicivirus
Lagovirus	Rabbit, hare, pig?, dog?, human? fox? mouse? bird?	Rabbit hemorrhagic disease virus of Europe, Asia, Australia, New Zealand; European brown hare syndrome virus
Vesivirus	Pig, cat, chimpanzee, sea lion, dolphin, mussel, sea otter, raccoon, Aruba Island rattlesnake, human	A48; feline caliciviruses F4, CFI, F65, F9; Pan-1, Tur-1; San Miguel sea lion virus types 1 to 17; SMSV-5 Hom-1
Nebovirus	Bovine	Newbury-1 virus

*Previous names of these genera were Norwalk-like and Sapporo-like viruses; synonyms for *Norovirus* and *Sapovirus* were small, round-structured viruses and typical caliciviruses, respectively.
Data from references 12, 69, 176, and 177.

domains (S and P) linked by a hinge. The S domain is responsible for the shell structure of the capsid, and the P domain protrudes from the shell, generating spikes that denote the "cuplike" depressions giving the name to this family.[34,160] The genomic RNA is covered by the capsid and remains covalently attached by its 5′ end to the viral genome–linked protein (VPg).[46]

Taxonomic Relationships Among the Caliciviruses

Caliciviruses were classified as picornaviruses when first identified. However, the International Committee on Taxonomy of Viruses decided to separate them, thus the *Caliciviridae* family was created in 1978.[41] Hepatitis E virus was initially included in the *Caliciviridae* until 1999, when it was separated.[13,130] The *Caliciviridae* currently comprises five genera: *Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*, and *Nebovirus*.[89,127]

According to the 2011 report of the International Committee on Taxonomy of Viruses, the following species are recognized within each genus: Norwalk virus for *Norovirus*, Sapporo virus for *Sapovirus*, feline calicivirus and vesicular exanthema of swine virus for *Vesivirus*, European brown hare syndrome virus and rabbit hemorrhagic disease virus for *Lagovirus*, and Newbury-1 virus for *Nebovirus* (Table 168-1). In addition, according to sequence analysis of whole-genome and capsid regions, multiple genogroups, denoted by "G" plus a roman number (e.g., genogroup two is denoted as GII), and genetic clades, named by arabic numbers following the genogroup name (e.g., GII.4 for genotype 4 of genogroup II) of uncertain biologic significance have been identified within each genus.

Genomic Organization

The genomic organization among the calicivirus genera differ in the number and size of open-reading frames (ORFs), the presence of certain genes, and the need for posttranslational cleavage for gene product function

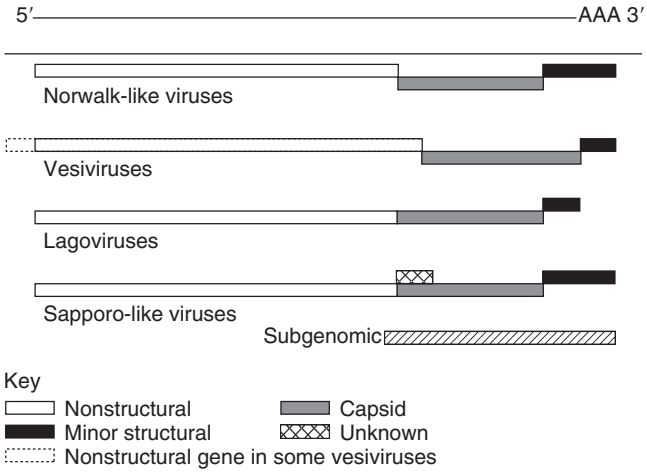

FIGURE 168-2 ■ Genomic organization of calicivirus genera. The genome of *Norovirus* has three open-reading frames (ORFs) that in the 5′ to 3′ direction include a nonstructural polypeptide, the virion capsid gene, and a minor structural protein. The genomes of the other three genera differ from that of noroviruses in the length of the ORFs, including a unique gene at the 5′ end of ORF1 in some vesiviruses and a posttranslationally cleaved N terminus of the capsid protein in vesiviruses and sapoviruses. A subgenomic RNA beginning just 5′ of ORF2 and continuing to the poly-A tail is synthesized during replication. Some sequence comparisons suggest that the longer ORF3 of *Norovirus* (and the comparable gene of *Sapovirus*) arose by intragenic recombination.

(Fig. 168-2).* The genomes of noroviruses and vesiviruses have three ORFs. ORF1 encodes a polyprotein cleaved by a viral protease during replication into a set of nonstructural proteins, including the RNA-dependent RNA polymerase (RdRp), the nucleoside triphosphatase, the protease, and the VPg; ORF2 encodes the capsid protein; and ORF3 encodes a protein that appears to be a minor structural protein.[79,94] Some vesiviruses strains

*References 28, 50, 94, 133, 165, 182.

differ from noroviruses in harboring a longer genome (e.g., Pan-1),[164] although this is not universal (e.g., feline calicivirus).[28] This longer genome includes a longer ORF1 with an additional predicted protein at the N terminus (p6),[148] a longer ORF2 with extra nucleotides at the 5′ end, which are posttranslationally cleaved, and a shorter ORF3 (approximately half the size of that of noroviruses.[148] ORF2 and ORF3 genes of these genera are included in a subgenomic RNA that can be transcribed independently to the genomic RNA.[94,164]

Sapoviruses, lagoviruses, and neboviruses have two ORFs. ORF1 is a fusion of the corresponding ORF1 and ORF2 of noroviruses and vesiviruses, whereas ORF2 encodes for a minor structural protein.[147,152] An additional ORF, in another frame, at the 5′ end of the capsid gene is present in some strains of sapoviruses.[147]

Calicivirus genomes have a highly conserved nontranscribed nucleotide sequence at the 5′ end of the whole genome and at the 5′ end of the capsid gene.[108] In addition, many caliciviruses have an overlap between the 5′ end of ORF1 and the 3′ end of the ORF2. Both features of genomic organization eventually favor recombination (see later discussion).[22] Conserved sequences of some regions of the capsid gene have been appropriate targets for primer design used in reverse-transcriptase polymerase chain reaction (RT-PCR) assays. Sequence analysis of these fragments has allowed accurate discrimination between genus and genogroups, equivalent to whole-genome sequence analysis.[213]

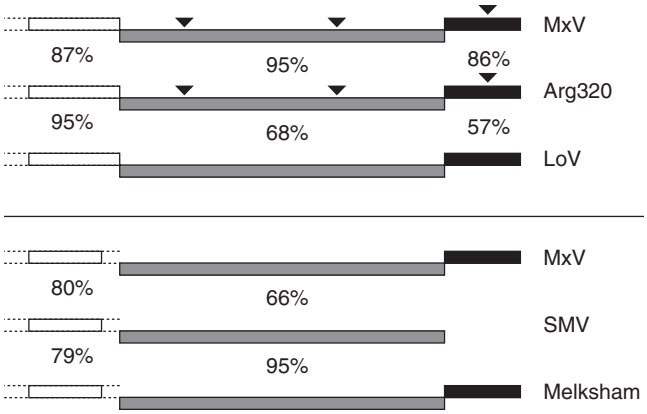

FIGURE 168-3 ■ Sequence comparisons of Argentine calicivirus strain 320 (Arg320; *top*) and Snow Mountain virus (SMV; *bottom*), each with two other noroviruses. Arg320 is significantly closer to Lordsdale virus (LoV) than to Mexico virus (MxV) in the RNA polymerase genome region and significantly closer to MxV than LoV in the capsid and ORF3 genes. Deletions or insertions in the capsid and ORF3 genes of Arg320 are shared with MxV but not with LoV. SMSV is equally close to MxV and Melksham virus in the known polymerase region but much closer to Melksham than MxV in the capsid region. The ORF3 sequence is not available for SMV. Box shadings are as in Figure 168-2. (Data from references 80 and 91.)

Recombinants

Evidence for Recombination Within Caliciviruses

The description of distinct phylogenetic clades within *Caliciviridae* genera and discrepancies of genotyping of some strains when RdRp and capsid sequences were analyzed independently encouraged studies aimed to recognize strains that might be natural recombinants within caliciviruses. Two examples are the well-characterized Argentine strain 320 (Arg320) and the prototype Snow Mountain virus, recognized in the 1990s to be recombinants, at the time when the RdRp and capsid regions of these strains were characterized (Fig. 168-3). In both strains, the change in relative sequence identity took place at the ORF1/ORF2 junction, where sequence conservation at the 5′ end of the genome also occurs (see earlier description), thus indicating that the recombination site occurred in this region. For Arg320, the ORF1 sequence had the highest identity with the Lordsdale virus (prototype of GII.4 genotype) and the capsid and ORF3 sequences had the highest identity with the Mexico virus (prototype of GII.3 genotype), both circulating simultaneously with strain Arg320. A similar change in relative sequence identity also occurred with Snow Mountain virus, which was detected when partial RdRp and capsid sequences were compared with reference Mexico (GII.3) and Melksham (GII.2) viruses respectively, again strains circulating during the same time period.[79,93] After the description of these recombinant strains, multiple naturally recombinant noroviruses and sapoviruses have been identified worldwide.[78,120,126,203] Although this phenomenon has been described also in vesiviruses, lagoviruses, and neboviruses, it seems to be much more infrequent in these genera.[42,49,57]

Other than recognizing a recombinant genomic structure, the recombinants themselves seem unremarkable in terms of clinical consequences. Recombination may be a mechanism by which caliciviruses quickly escape host immunity, analogous to antigenic shifts among influenza viruses but by a different molecular mechanism. The recombination event could be recent or have occurred in the remote past.

Generation of recombinants within caliciviruses requires certain biologic and molecular attributes. First, the infection of single cells simultaneously by two calicivirus strains, in absence of immune or molecular interference. Outbreaks caused by multiple *Norovirus* strains and coinfection with different *Norovirus* strains occur.[11,59,62,89] Second, the genomic structure of caliciviruses favors recombination, owing to overlapping regions between ORFs, conserved regions at 5′ end of the ORFs, and independent transcription of high copy number of the subgenomic region. Finally, the calicivirus RdRp can recognize and process the highly conserved 5′ end sequence of both ORF1 (for whole-genome transcription) and ORF2 (for subgenomic transcription) and can eventually switch from one RNA molecule to another.[22] The recognized recombinants may be a viable subset, among a larger set of recombination events occurring during replication.

Antigenic Properties of the Virion

The presence of a single main capsid protein theoretically ought to limit the antigenic complexity of the virion. However, circulating caliciviruses are highly diverse.[78,84,100,120] This diversity is explained, as in other

RNA viruses, mostly by the high error rate in genomic transcription performed by the viral RdRp, which has no proofreading activity.

Many vesiviruses can be cultivated readily in cell culture, whereas cultivation of viruses in the other genera has been successful for only a few strains.[53,56,181,185] The vesiviruses include a large number of serotypes (>40 neutralization types).[176] Similarly, characterization of lagoviruses suggests the existence of serotypes.[144,207] Determination of whether the other genera have similar diversity has not been possible because of the lack of ability to test strains for their neutralization characteristics. Antigenic characterization of caliciviruses is at a primitive level of development.

Even though no human calicivirus have been successfully cultivated to date, reverse genetic systems and recombinant technology developed to express capsid protein in different cell lines have allowed studies on virus assembly and characterization of antigenic properties of viral capsids.* Enzyme-linked immunosorbent assays to detect viral antigens and antiviral antibodies directed against specific strains have been developed.[74,96] An intense, clear reaction is usually evidenced for the specific strain, but frequent cross reactivity between genotypes and genogroups have also been reported.[77] Neutralization assays have not been performed for human calicivirus because of culture limitations; however, innovative receptor (histoblood group antigen [HBGA]) blocking assays, and hemagglutination inhibition assays have demonstrated a high correlation between blocking/inhibiting antibody titers and protection against a specific strain.[44,163]

NOROVIRUS AND *SAPOVIRUS*, HUMAN CALICIVIRUSES

Strains commonly recovered from human gastroenteritis illness fall into two genera: *Norovirus* (mainly GI and GII) and *Sapovirus*, the called human caliciviruses. Noroviruses and sapoviruses share a number of properties. To avoid repetition, we will discuss features common to both genera followed by distinct features for each genus.

Epidemiology

Human caliciviruses have worldwide distribution, and serologic studies indicate that infections by these agents occur commonly and early in life, with virtually all individuals having antibodies at 5 years of age.[67,145,152]

Human caliciviruses are described as causing acute gastroenteritis mainly in two distinct situations, sporadic endemic cases affecting children younger than 5 years of age and as a cause of outbreaks affecting individuals of all ages. *Norovirus* is the second cause of endemic acute diarrhea in children after rotavirus (before rotavirus vaccine introduction), causing 10 to 20 percent of overall cases and near 20 percent of diarrhea-associated hospitalizations.[5,20,36,154] *Sapovirus* is comparatively less frequent, accounting for 1 to 10 percent of endemic gastroenteritis.[132,192,195]

Noroviruses are the main cause of gastroenteritis outbreaks, associated mostly with contaminated water and food, particularly shellfish.[5,107,187] Noroviruses account for approximately 50 percent of all outbreaks in countries with adequate sanitation and more than 90 percent of outbreaks for which no bacterial or parasitic cause can be found.[5,30,107,187,204] Unlike noroviruses, sapoviruses are known primarily from sporadic cases of diarrhea in children, although outbreaks in closed populations do occur.[113,190] Most of human caliciviruses outbreaks are recognized in close settings where common exposure occurs, such as nurseries, childcare centers, schools, hospitals, camps, hotels, and ships. In these outbreaks, in addition to the primary source (contaminated water or food), person-to person spread also plays a significant role in prolonging outbreak duration. Long persistence of norovirus gastroenteritis outbreaks has been described and has been associated with persistent asymptomatic excretion in food handlers, continual surface contamination, and reexposure to the same strain from contaminated foods.[37,52,105] Primary attack rates in outbreaks frequently are high, near 30 percent, and secondary attack rates range from 5 to 30 percent.[65,206]

Although, high genetic and antigenic diversity have been described for human caliciviruses, mainly for *Norovirus*,[60,77,85] a clear predominance of specific genotypes has been described and large changes in the relative prevalence of these genotypes have occurred during the past 40 years.[5] For example, Norwalk virus, prototype of GI.1 strains, and closely related strains appear to have been the predominant noroviruses in the 1970s in several regions studied.[71] Thereafter, Snow Mountain virus (prototype of GII.2 strains) and related strains predominated, whereas strains within the clade that contains the prototype Norwalk virus (GI) were found infrequently (<5%).[5,100,125] Since the mid 1990s, GII.4 strains emerged and globally spread, representing currently more than 80 percent of noroviruses identified.[114,143,162,174] Distribution of GII.4 lineages differs remarkably from region to region and/or over time, which could be at least partially explained by selective pressure due to population-acquired immunity.[23,114,174]

Seasonal Patterns

Both sporadic and outbreak-associated *Norovirus* infections have winter seasonality (Fig. 168-4).[70,129,138,214] Exceptions to this trend are observed for particular transmission sources. Infections related to certain food will occur when harvested and eaten fresh (fruit, salads, shellfish) or processed, shipped, and consumed later (frozen fruits, ice).[7,30,169] Infections from exposure associated with recreation facilities, such as swimming, tend to have a summer seasonal predominance.[168,188] In addition, contamination of water supplies occurs more frequently in a flooding situation resulting in the mixing of clear water and sewage and in situations associated with shellfish harvesting.[8,119,158,198]

A distinct seasonal prevalence of *Sapovirus*-associated illness is not as apparent, but winter predominance is suggested from several studies.[48,154,214]

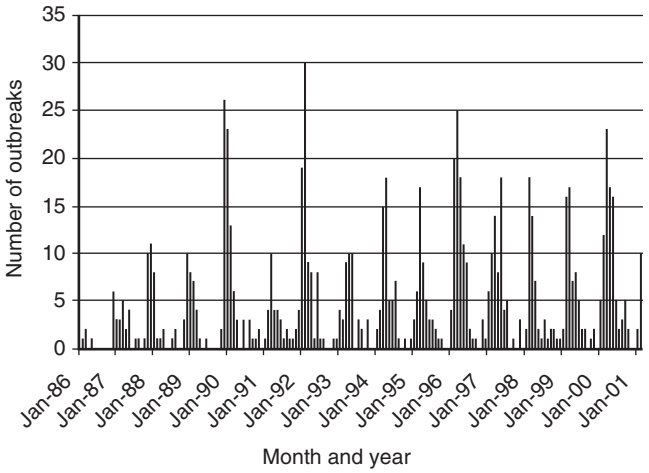

FIGURE 168-4 ■ Seasonality of 840 presumed viral outbreaks in nursing homes for the elderly in Maryland, 1986 to 2000. Detailed analyses of 20 outbreaks found noroviruses in 18. (Data from Figure 1 in Green KY, Belliot G, Taylor JL, et al. A predominant role for Norwalk-like viruses as agents of epidemic gastroenteritis in Maryland nursing homes for the elderly. *J Infect Dis* 2002;**185**:133-46.)

Pathogenesis, Pathology, and Immunology

Pathogenesis

Human calicivirus have not been successfully cultivated in cell lines to date, and animal models are still under development, a situation that has hindered pathogenesis elucidation. Most of the information in this area comes from human volunteer studies, in vitro assays with virus-like proteins (VLPs), and animal models infected with murine norovirus.

Human volunteer studies performed in 1970s showed a group of individuals who seemed resistant to Norwalk virus infection after challenge even with high viral doses.[5,158] The mechanism proposed for this differential risk was the absence or presence of HBGAs on digestive mucosa that could act as a host receptor. HBGAs are oligosaccharides present in human secretions and epithelia and are part of the innate immune system. The expression of HBGAs on mucosa is controlled by the activity of a fucosyl transferase (FUT2), which is responsible for the synthesis of H antigen, the precursor of the A and B antigens. Individuals carrying an inactivating mutation of FUT2 do not express HBGAs on their epithelia, are eventually resistant to *Norovirus*, and are named nonsecretors, whereas subjects with normal active FUT2 express these oligosaccharides and are denominated secretors. More recently, volunteer challenge studies, epidemiologic surveys, and in vitro assays have supported the role of these sugar structures in *Norovirus* virion attachment.* A genogroup-specific HBGA-attachment pattern has been described in vitro that could be related with strain-specific susceptibility.[87,116]

Secretor status does not completely explain the differences seen among infected and uninfected individuals for all *Norovirus* strains. Additional mechanisms are likely involved and remain an ongoing field of research.

*References 19, 87, 109, 116, 121, 200.

Pathology

Knowledge about pathogenic mechanisms of human calicivirus has been limited by the lack of an accurate animal model. Small bowel biopsy specimens obtained from *Norovirus*-infected volunteers in challenge studies mainly evaluating the prototype Norwalk virus have given some pathologic clues.[4] Villous atrophy, epithelia disarrangement, crypt hyperplasia, cytoplasmic vacuolization, and lamina propria inflammatory infiltrate have been described in duodenal/jejunal biopsy specimens obtained from Norwalk virus–infected individuals.[2,5,157,170,171] These morphologic changes have been evidenced both in symptomatic and asymptomatic infected subjects and as early as few hours before starting of clinical manifestations. No viral particle or specific cytopathic effects in enterocytes have been described. Histologic changes resolve after 2 weeks in immunocompetent individuals but could take months in immunosuppressed patients.[5,136,157] Sucrase, trehalase, and alkaline phosphatase activities from the intestinal brush border of symptomatic patients are decreased, inducing a transient malabsorptive state.[2]

The pathogenic features of *Sapovirus* infection in humans have not been determined and are presumed to be the same as those for *Norovirus* caliciviruses.

Immunology

The first barrier against human calicivirus is innate immunity, mainly represented by HBGA on enterocyte surface, which acts as host receptors (see earlier). Nonsecretor individuals lacking HBGA on their epithelia have a lower risk of *Norovirus* infection and *Norovirus*-associated gastroenteritis.[5,19,116,200] HBGAs present in human breast milk can inhibit the binding of noroviral VLPs to saliva and synthetic oligosaccharides in vitro; breast-fed infants from secretor mothers have a lower risk of gastroenteritis caused by *Norovirus* compared with other enteric pathogens.[94,137]

Although human calicivirus infection triggers both humoral and cellular immune acquired responses, infection by these agents can occur many times in the same individual and at any age. Protective acquired immunity to *Norovirus* seems to be complex and remains incompletely understood. Volunteer and clinical studies have demonstrated that 2 to 3 weeks after *Norovirus* infection, serum specific antibodies can be detected and persist for many months.[43,116,157] Adult individuals rechallenged by the same strain seems to be protected shortly after (6 to 14 weeks) the initial exposure but can be infected again when the exposure occurs 24 to 72 months after the first challenge.[5,157] Cross reactivity has been described, but it seems to be restricted to strains of the same genogroups.[115,209] It has not been possible to correlate specific antibody titers with protection, and individuals with high serum and duodenal titers challenged with the same strain of *Norovirus* can even be more susceptible than subjects who have lower titers or are seronegative.[15,97] However, the viral infectious dose given to volunteers in

these challenge studies was severalfold greater than naturally occurring infective doses and thus may not actually represent the phenomenon of natural immunity.

Viral neutralization assays have not been possible, owing to the lack of an adequate cell culture system. HBGA blocking assays and hemagglutination inhibition assays strongly suggest that natural infections are followed by the production of strain-specific protective antibodies.[44,163]

Clinical Manifestations

The incubation period after exposure to *Norovirus* ranges from 12 to 60 hours, with a mean of 24 hours.[6,66,199] Stool excretion of *Norovirus* begins as early as 15 hours after the development of infection, peaks during the second day, and persists at least 7 days and up to 2 months.[6] Noroviruses also have been detected in vomitus, thus suggesting the possibility of spread by aerosol or dispersion of vomitus particles.[31,122] Illness is usually characterized by a self-limited episode of nonbloody diarrhea, nausea, vomiting, and low fever, lasting 1 to 2 days in outbreak setting and 5 to 6 days in endemic cases.[88,165] In children older than 1 year of age, vomiting predominates, whereas in infants and adults, diarrhea tends to predominate.[5,65] This clinical presentation is indistinguishable from those of other enteric pathogens.

A wide disease spectrum ranging from asymptomatic excretion to severe disease with dehydration requiring hospital admission can occur for human caliciviruses as for all enteric viruses; death from *Norovirus* illness rarely occurs.[6,21,65,150,165] In general, human calicivirus gastroenteritis cases are milder than rotavirus cases, even though these agents may represent up to 20 percent of diarrhea-associated hospital admissions in children younger than 5 years of age.[151,214] Chronic symptomatic infections have been described in immunocompromised individuals.[58,142,167] Although the predominant feature of human calicivirus infections is by far gastrointestinal, some researchers have described viral RNA in serum samples, suggesting the possibility of occasional systemic infections; febrile and nonfebrile seizures during norovirus gastroenteritis have been described.[32,35,193] Specific factors associated with clinical severity have not been clearly identified; GII.4 *Norovirus* strains were associated with more severe cases in one study.[21]

Sapovirus illnesses are also indistinguishable from those caused by other gastroenteritis pathogens with a wide spectrum of severity, although most gastroenteritis cases are mild.[48,61,132] A few children in one study intensively evaluated during hospitalization for a *Sapovirus* illness had prolonged malabsorption, frank rectal bleeding, severe dehydration and acidosis, and transient leukopenia.[18]

Differential Diagnosis

In sporadic cases, human caliciviruses are almost indistinguishable by clinical presentation from other viral and toxic causes of gastroenteritis. Persons with calicivirus-associated infections tend to have less fever and more vomiting than if infected with other agents.[5,123,151,214] Characteristic human calicivirus outbreaks are associated with a rapid onset of symptoms after contaminated water or food ingestion (24 to 48 hours of incubation), high primary and secondary attack rate, and a broad age range of affected individuals. The pattern of symptoms is a fairly good marker for calicivirus-associated outbreaks: a brief duration of illness, 2 to 3 days; vomiting as a prominent symptom in more than 50 percent of the outbreak cases; and cultures of freshly processed stool specimens negative for bacterial, parasitic, or fungal pathogens.* When outbreaks have such characteristics, noroviruses will be detected in more than 80 percent.

Diagnosis

Molecular and immunologic based techniques have been developed for human calicivirus detection in both clinical and environmental samples.

Real-time quantitative RT-PCR assay directed against the ORF1-ORF2 junction (a highly conserved region) is currently the most sensitive test for *Norovirus* detection in both stool and environmental samples,[45,99,153,191,201] and can be applied in endemic and outbreak gastroenteritis cases. Cautious interpretation has to be given to detection of very low viral loads, because asymptomatic excretion is common.[151] This assay discriminates between genogroups (GI and GII) but not between subtypes, which may make epidemiologic studies and tracking of a potential infectious source in outbreaks difficult.[45,191] Technical modifications for simultaneous screening of high number of samples (one-step and duplex assays) and simultaneous detection of multiple enteric pathogens have been developed.[55,83,153,201]

Conventional RT-PCR was the main diagnostic technique until the mid 2000s, after which it has been largely replaced by the highly sensitive and faster real-time assay; currently its main application is on nucleic acids amplification for DNA sequencing and genotyping.[30] The gold standard for *Norovirus* genotyping is full capsid sequencing; however, this procedure is very time consuming and technically difficult, making it impractical in clinical and epidemiologic settings.[213] Four conserved genomic regions, specifically from the RdRp and capsid genes (designated regions A to D), have been used successfully for *Norovirus* genotyping.[93,205] Genotyping based on the capsid gene, particularly on region D, allows better discrimination between strains, with only slightly less differentiation when compared with the full capsid sequencing, which is the reason why it is more practical for clinical sample analysis.[30]

Enzyme immunoassays (EIAs) for stool antigen detection have been developed, and commercial kits are currently available.[29] Among the advantages of these methods are their high specificity, lower cost, and lower requirements for skilled personal and complex instruments[30]; the disadvantage is their lower sensitivity due to a high antigenic diversity of human caliciviruses and a low stool viral load that can be under the threshold of detection. Compared with RT-PCR, the sensitivity of new-generation commercial EIA kits ranged from 61 to 80 percent, and

*References 8, 30, 65, 75, 102, 117.

specificity has ranged from 92 to 100 percent.[64,104,106,135] Because of the modest sensitivity of these commercial kits, they are not currently recommended for *Norovirus* detection in sporadic gastroenteritis cases. However, given their ease of use and rapid results, these methods have been recommended for screening of multiple stool samples obtained from gastroenteritis outbreaks; negative results do not exclude *Norovirus* etiology, and molecular tests should be performed in outbreak situations.

Immunochromatographic rapid tests have also been developed. The advantages of these methods are their potential use as point of care tests to provide rapid results. However, their low sensitivity (near 70%) currently limits their clinical application.[64]

VESIVIRUS

Epidemiology

General Prevalence

Vesiviruses include a large number of serotypes isolated from many different animal hosts, including pigs, cows, cats, dogs, sea lions, sea otters, walruses, whales, several snakes, pygmy chimpanzees, and gorillas, as well as a few isolates from humans.* These viruses probably have a worldwide distribution in terrestrial and marine environments, although studies of San Miguel calicivirus–like strains are lacking outside North America. Vesiviruses include at least 40 neutralization types (serotypes). The prevalence of these serotypes in different regions has had little study.

Morbidity and Mortality

Vesiviruses cause a variety of severe illnesses in animals and are not currently considered a relevant human pathogen, with rare cases reported mainly in people with close exposure to animals. Nevertheless, a role in human disease cannot be excluded because anti-*Vesivirus* antibodies were detected in 12 percent of normal blood donors, at higher prevalence (21%) among otherwise normal donors with elevated serum levels of liver aminotransferases and at highest prevalence (47%) among patients with hepatitis associated with blood exposures.[179] Some individuals in the groups with normal and elevated aminotransferase levels also had *Vesivirus* RNA circulating in the blood. The exact clinical significance of this finding from one study is still unclear.

One laboratory worker was infected with SMSV-5 and experienced an influenza-like illness, followed during the next several days by viremia and a vesicular exanthem similar to that observed in the original pinniped host.[177] SMSV-5 was visualized in vesicular fluid by electron microscopy and was cultured from the lesions; the genome was amplified and sequenced. The worker also mounted a greater than fourfold serum neutralizing antibody response to SMSV-5. Biologists working with marine mammals had similar illnesses but were studied less intensively than was the laboratory worker.[11,182]

*References 12, 54, 63, 124, 176, 178, 183, 186.

Host and Social Factors

Although vesiviruses cause a variety of diseases, only a few strains cause gastroenteritis, a feature common to *Norovirus* and *Sapovirus* caliciviruses. Among the vesiviruses are a number that exhibit a broad range of hosts. For example, SMSV-5 has been found to infect sea lions, seals, opal-eye fish, pigs, cattle, and laboratory workers.[176,184]

Pathogenesis and Pathology

Vesiviruses cause infection on mucosal surfaces (pneumonia, aphthous ulcers) and disease after viremia (generalized vesicular eruption, encephalitis, hepatitis, spontaneous abortion). The incubation period after exposure is short: 1 to 4 days.[189] Excretion varies among species. For three cultivable vesiviruses, asymptomatic and persistent excretion of virus was detected for months after the primary infection.[98,181,185]

The pathogenic features of *Vesivirus* infection vary and depend on the syndrome of the affected host.

Clinical Manifestations

The proven clinical manifestations of *Vesivirus* infection in humans are limited to a few cases. Because vesiviruses cause a variety of illnesses in animals and these viruses occur naturally in primates, the potential spectrum of illness in humans is broad. Groups at greatest risk of acquiring infection probably would be zoo workers, indigenous populations handling marine mammals, veterinarians, and laboratory workers, but studies of these groups have been limited.[183] The clinical implications of the finding of anti-*Vesivirus* antibody and RNA in serum are uncertain. The RNA in serum was found in persons judged well enough to donate blood.[179]

Diagnosis

Many vesiviruses can be cultivated in cell culture, and many are found in sufficiently high concentration in clinical samples to permit the use of electron microscopy and classic virologic methods for detection of infecting viruses. Other strains have resisted cultivation, and molecular techniques have been developed for them.[127,141,173] Vesiviruses are heat labile, and clinical samples should be submitted promptly and unfrozen for analysis.

LAGOVIRUS

Epidemiology

General Prevalence

The prototype *Lagovirus* is RHDV. Lagoviruses include the genetically distinct European brown hare syndrome virus and multiple genetically distinct strains recovered from asymptomatic rabbits.* Rabbits also are infected

*References 25, 26, 110-112, 207, 210.

with *Vesivirus* strains, which may lead to confusion.[124] Antigenic diversity occurs in the *Lagovirus* genus, but the number of serotypes in the genus is unknown, because like noroviruses and sapoviruses, lagoviruses cannot be cultivated in the laboratory.[207] RHDV has been epidemic in Asia and Europe since it was first recognized in China in 1984.[210] Rabbits in more than 40 countries have been affected. Disease spreads rapidly and appears to "leap" large distances in a short time. The ability of the virus to spread rapidly across large bodies of water (e.g., the English Channel) suggests that arthropods or other flying vectors have a role in transmission.[33] One outbreak in Mexico was traced to a shipment of rabbit meat from Asia; extensive slaughter of rabbits in Mexico was required to eradicate the agent.[68] Three outbreaks have occurred in North America and Cuba.[24] The source of these outbreaks is unknown, although deliberate importation and release was suspected.

RHDV was released in 1995 in controlled field studies off the coast of mainland Australia but escaped from the study site the same year and spread onto the continent.[90] Subsequently, the virus was introduced illegally into the South Island of New Zealand. Clandestine, deliberate spread in both countries to control exotic European rabbits led to wide dispersal of the agent. These releases occurred despite conflicting evidence of RHDV infection in other animal species and, subsequently, in humans.[27,128]

Morbidity and Mortality

Lagoviruses are not currently considered a human pathogen. RHDV infections are highly fatal (>80%) in wild and domesticated European rabbits. Subclinical infections occur in young rabbits, and immunity from early infection appears to attenuate later exposure. In the food-associated outbreak in Mexico, antibody developed in one human. Zoo workers, rabbit breeders, and foresters would have the largest occupational risk of RHDV exposure. The human infection in the Mexican outbreak apparently was subclinical.[68] Ostensibly, subclinical infection also occurred in some persons exposed to rabbits in Australia after escape of the virus there.[128]

Host and Social Factors

The range of hosts of lagoviruses and the host of RHDV before it was recognized in rabbits in China are unknown. In Australian studies, numerous Australian animal species challenged with a subimmunogenic dose of RHDV had no antibody response. On the other hand, antibodies did develop in kiwis, mice, dogs, and foxes; in the case of foxes, the serum antibody response was attributable to oral feeding.[39] Natural spread in rabbits is enhanced by their colony breeding behavior.

Clinical Manifestations and Pathogenesis

The incubation period after exposure is 1 to 3 days.[202] Lagoviruses cause a fatal hepatitis in rabbits and hares that results in disseminated intravascular coagulation and diffuse hemorrhage. Death is rapid, occurring 6 to 12 hours after the onset of illness. RHDV and European brown hare syndrome virus appear to be sufficiently distinct to preclude cross protection. Because the infections in the Mexican worker exposed during the RHDV outbreak and in the workers in Australia who tested antibody positive apparently were subclinical, the spectrum of potential infection in humans is unknown.

Diagnosis

Samples from persons with suspected infection should be submitted to reference laboratories after consultation. Diagnosis can be established with immunologic and molecular techniques.

NEBOVIRUS

Epidemiology

Nebovirus and its prototype strain Newbury-1 virus are bovine pathogens, causing acute gastroenteritis mainly in calves.[103,149,155,175] Although the first report of these bovine pathogens was in the mid 1970s, they were not recognized as a different *Caliciviridae* genus until recently[103,149,175,208] Neboviruses have been detected in 3 to 10 percent of calves with diarrhea[82,103] and have not already been isolated in humans.

Clinical Manifestations and Pathogenesis

After 1 to 3 days of incubation, a self-limited acute nonbloody diarrhea manifests and lasts less than 7 days.[76,175] The histologic damage predominates in the proximal small bowel and is characterized by stunted villi and a decrease in galactosidase activity, and carbohydrate absorption has been demonstrated in challenge studies with gnotobiotic calves.[76]

Diagnosis

Bovine stool samples are processed by RT-PCR for *Nebovirus* detection.[103]

TREATMENT AND PREVENTION

Nonspecific Measures

Children with diarrhea are more likely than are children without diarrhea to be excreting enteric viruses, including caliciviruses. Infection with noroviruses requires a very small inoculum, on the order of 100 particles, which favors transmission in closed setting and through fomites.[30,51,118,199,209] For children in care settings as well as for hospitalized children, a few infection control measures are likely to reduce the spread of infection. Such measures include personnel trained in hygiene and isolation procedures, cleanliness of surfaces (with sodium

hypochlorite solution or 70% ethanol) and in food preparation, exclusion of ill care providers, adequate hand washing, and exclusion or cohorting of ill children.[30,51,73] Laboratory workers exposed to caliciviruses should be aware of the risk for acquiring infection.

Specific Measures

No specific treatment for calicivirus infection has been established. Feline interferon and ribavirin inhibit the replication of feline calicivirus (a *Vesivirus*) in feline cell lines.[134,159] Morpholino antisense oligomers blocked production of *Vesivirus* and murine norovirus virions cultivated in cell lines and inhibit the protein expression of Norwalk virus in replicon-bearing cells.[17,188] These antisense compounds have potential for prophylaxis and treatment of illness, although their potential future clinical use in humans seems highly unlikely.[180] More recently, a nucleoside analog, 2′-C-MeC, showed significant in vitro activity against a GII norovirus prototype and could be further explored for human use.[40] Use of HBGA receptor blocking molecules has also been postulated as a possible therapeutic strategy for the future.[139]

Vaccines for feline calicivirus and RHDV indicated that this prevention method could work for other caliciviruses. The development of human vaccine candidates has focused on noroviruses with substantial advances during the past decade. *Norovirus* vaccines incorporating an immunogen-expressed capsid protein that self-assembles into VLPs have been the candidates most extensively studied.[4,9,10,72,194] More recently, viral particles formed specifically by the P domain of the capsid protein (P particles) have been studied as potential vaccine candidates.[197]

A safe and effective *Norovirus* vaccine could play a significant role in reducing the impact of large gastroenteritis outbreaks occurring in specific settings in which large groups of individuals are compromised. Army personnel especially those allocated to large ships, foreign aid workers, cruise ship workers, and residents of elder care facilities are examples of populations that could benefit from *Norovirus* disease prevention.[51] More importantly, a vaccine targeted for infants, following the age strategy used for rotavirus, could have a significant impact in further reducing the toll from death, hospitalization, and medical visits associated with childhood endemic gastroenteritis. Current epidemiologic data indicate that an effective vaccine could reduce up to 20 percent of emergency department visits or hospitalizations associated with gastroenteritis.[151]

Barriers to *Norovirus* vaccine development have been related with the perception that immunity is short termed and strain specific and that the significant genetic/antigenic variability may impair the effectiveness of a vaccine including a limited number of antigenic variants. The concept of short-term immunity was obtained from challenge studies in adults[157,209]; the situation in children may be different. A cohort study in infants from Chile indicates that *Norovirus* infections and reinfections are very common and caused largely by GII strains but that symptomatic reinfections are uncommon during the first 3 years of life. Not a single case of a symptomatic GII infection was detected.[150] Thus, similar to rotavirus, it is possible that a GII *Norovirus* vaccine would be protective against symptomatic disease during the first critical 3 years of life and probably less protective against asymptomatic and mild infections. This vaccine outcome would be of unquestionable epidemiologic benefit worldwide.

The most advanced *Norovirus* vaccine candidate is a VLP formulation in a powder form for intranasal use or in a formulation for parenteral use.[4] Intranasal administration in a placebo-controlled trial including 90 adults receiving two doses of a Norwalk virus G1.1 VLP or placebo demonstrated a 70 percent immunoglobulin A antibody response in vaccine recipients. A Norwalk virus challenge caused gastroenteritis in 69 percent of placebo recipients and in 37 percent of vaccinated individuals ($p = .006$), whereas infection occurred in 82 percent and 61 percent, respectively ($p = .05$). These results are encouraging and open a path for the development of GI and, more importantly, GII vaccines for infants.

P-particle–based vaccines may be less immunogenic and thus far seem less likely to succeed as a vaccine. The advantage of this approach is the possibility of combining different antigens such as rotavirus and influenza virus[196,197] in a parenteral vaccination strategy, although antigen combination also seems feasible for VLPs, at least with rotavirus VP6 antigen.[16] In any case, these potential strategies are at least 5 years away from being implemented.

PROGNOSIS

Understanding of the features of calicivirus infection in humans has increased rapidly since 1990, when molecular tools for studying the viruses became available. The availability of refined diagnostic techniques has significantly increased our understanding of calicivirus-associated disease. Gastroenteritis that is mostly mild to moderate, but also severe, is the sole recognized disease associated with these viruses in humans. Severe cases have been reported mostly in infants, elder adults, young healthy men under physical stress (e.g., military personal), and immunocompromised patients.[47,58,150,167] Disease is usually short-lived with the exception of infection in immunocompromised individuals, including children with solid-organ transplants, in whom it can cause prolonged diarrhea and viral shedding for months.[58,166] Severe chronic diarrhea can also occur in children with stem cell transplantation.[167] Deaths associated with *Norovirus* infections have been reported in adults with hematopoietic stem cell transplantation.[172] Nevertheless, these complications are rare, and most infected individuals fully recover within 1 week.

CHAPTER 169

Hepatitis E Virus

Ravi Jhaveri

Hepatitis E virus (HEV) was only recently characterized but has likely been infecting humans for hundreds of years. New information about the animal reservoirs, epidemiology, and molecular biology is constantly becoming available. Recent natural disasters and regional warfare have highlighted HEV as an agent that causes epidemics in areas where sanitation and public health systems have broken down. New developments offer hope that protection using vaccine will soon become a reality. This chapter is a summary of the discoveries so far with emphasis on the impact of HEV infection in children.

HISTORY

As methods to detect hepatitis A and B virus as the major causes of fecal-oral and blood-borne hepatitis, respectively, became more reliable in the 1970s, more cases were being classified as "non-A, non-B hepatitis." Investigations in regions of South Asia examined epidemic and endemic cases of acute hepatitis.[43,82,172] Case patients all had a clinical course that was very similar to that of hepatitis A virus (HAV), despite a remote history of HAV infection, and testing for other causes of viral hepatitis was negative. Many believed that a distinct enteric viral agent was the cause of these cases.

The first evidence of this came when Balayan and colleagues[18] used stool extracts from infected humans orally administered to a human volunteer known to be HAV immune. Classic hepatitis symptoms ensued, and stool from the infected volunteer was used to reinfect cynomolgus macaques. Electron microscopy of stool samples from the asymptomatic and early symptomatic phase showed virus-like particles (VLPs) approximately 30 nm in diameter that banded at 1.35 g/cm^3 on a cesium chloride gradient.[26,27] VLPs showed no cytopathic effect when passaged in tissue culture and mice inoculated with the VLPs showed no signs of disease.[18]

The field experienced a major advance after the reverse-transcriptase polymerase chain reaction (RT-PCR) identification of hepatitis C virus (HCV) in 1989.[32] Similar methods were used to determine the nature of the non-A, non-B enteric virus.[132] Reyes and colleagues[132] constructed cDNA clones from infected bile that subsequently hybridized with RNA from infected animal and human liver, as well as isolates from five distinct geographic outbreaks. Sequence analysis revealed the presence of an RNA-dependent RNA polymerase, a common feature of plus-strand RNA viruses. Northern blot hybridization identified a 7.4-kilobase (kb) molecule present only in homogenates from infected liver samples. The agent was pronounced "hepatitis E virus" and further efforts by the same group cloned and sequenced HEV during the subsequent year.[149]

MICROBIOLOGY AND GENOME ORGANIZATION

HEV is a plus sense RNA virus with a genome size of approximately 7200 base pairs (bps).[149,174] Initial cloning of the Burma strain revealed the presence of three overlapping reading frames (ORFs).[149,162] ORF1 is approximately 5000 bps in length and encodes for the nonstructural proteins.[89,149] ORF2 begins 37 bps downstream from the ORF1 stop codon and codes for the viral capsid.[149] ORF3 is only 369 bps and overlaps both ORF1 and ORF2. The viral RNA contains a short 5′ untranslated region (UTR) of approximately 27 bps and a 3′ UTR of approximately 65 bps.[149] The genome has a 7-methyl cap at the 5′ UTR and a poly-A tail of approximately 150 to 200 bases.[73] The organization of the genome is represented in Figure 169-1.

Initial comparative genomic analysis deduced the likely functions of the ORF1 nonstructural regions.[89] They include the methyltransferase "capping" motif (~amino acids 56-240), papain-like cysteine protease (~amino acids 433-592), RNA helicase (~amino acids 960-1204), and the RNA-dependent RNA polymerase (RdRp) (~amino acids 1207-1693). Details of ORF1 processing are limited, but recent data examining ORF1 using a baculovirus system showed extensive cysteine protease processing.[9,121,137] The enzymatic activities of the methyltransferase and RdRp have been demonstrated in independent studies.[7,100]

ORF2 codes for the viral capsid protein.[149] Specific studies of the ORF2 have shown a membrane export signal sequence (amino acids 1-36) at its extreme N-terminal, several glycosylation sites, and multiple smaller processed forms.[69,133,149,179] ORF2 has dimerization sites and can assemble into VLPs when the first 110 amino acids are deleted.[96,95,176] Studies have shown that ORF2 dimers can encapsidate and deliver exogenous HEV RNA to naïve cells.[122]

The role of ORF3 appears to be multifaceted. A key function of the protein appears to be in mediating viral egress from cells.[177] ORF3 deletion mutant viruses can replicate RNA, but this RNA is almost entirely intracellular. Specific studies have shown that a specific proline-containing motif within ORF3 is responsible for interacting with cellular Tsg101, which has also been shown to interact with several other viruses.[45,81,116] Other effects include interaction with the MAPK/ERK pathway, ORF2 binding, and self-association.[79,90,167,168] Recent studies have shown that ORF3 also mediates the evasion of interferon responses in A549 cells.[41]

Viral Structure and Stability

Electron micrographs from fecal samples of patients and animals infected with HEV show the virus to be approximately 27 to 30 nm in diameter.[18,26,27]

Ultrastructural studies of HEV have involved ORF2 expression, and the empty VLPs produced are slightly smaller than infectious HEV.[96,176] The VLPs assemble from 30 dimers to form a spiky hollow sphere.[176] Although the empty VLP shares much similarity with the native virion in appearance, further confirmation is lacking until a tissue culture system is available.

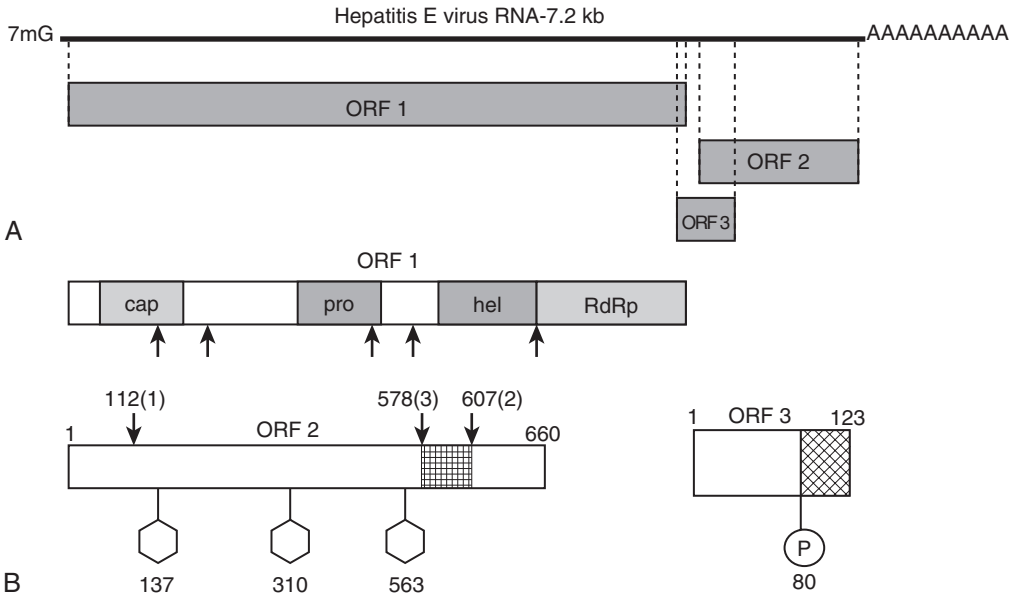

FIGURE 169-1 ■ Representation of HEV genome and open-reading frames. **A,** Hepatitis E virus (HEV) genome overview. The HEV RNA is single stranded and features three overlapping reading frames: ORF1, ORF2, and ORF3. **B,** Individual features of the HEV ORFs. ORF1 contains the nonstructural protein domains *(shaded),* which include the methyltransferase *(cap),* cysteine protease *(pro),* helicase *(hel),* and RNA-dependent RNA polymerase *(RdRp).* Proposed cleavage sites are illustrated with the *bold arrows* at their approximate locations. ORF2 is the structural capsid protein, which is 660 amino acids in length. Cleavage sites are indicated by the *bold arrows* at their determined amino acid positions. Glycosylation sites are represented with *polygons* at their determined amino acid positions. The domain of ORF2 that has been determined to be the neutralization epitope is represented by the *cross-hatched box.* ORF3 is the smallest protein, and its phosphorylation site is represented by the *circle labeled P.* The domain responsible for dimerization is represented by *the diagonal hatched box.*

Several strains of HEV are almost completely heat inactivated by 60°C (140°F), in contrast to 66°C (150.8°F) for HAV[44] with some interstrain variability. Virus-containing stocks have been stable at extreme cold temperatures with several freeze/thaw cycles.[44] Based on persistent HEV infections during an outbreak from water containing chlorine concentrations of 0.3 to 0.6 mg/L, HEV may be resistant to chlorine inactivation.[57]

Viral Life Cycle

For many years, HEV did not grow in tissue culture conditions, so detailed information regarding viral structure and life cycle were limited.[43] Limited studies have shown evidence of HEV replication in primary macaque hepatocyte cultures.[150,151] When in vitro transcribed RNA from a full-length cDNA clone was transfected into liver cell lines, viral proteins could be detected and the culture supernatant could be used to infect a rhesus monkey.[121] However, recent efforts have demonstrated that HEV clinical strains isolated from feces and blood can replicate to high titers in the PLC/PRF/5 liver cell line and the A549 lung cell line.[152] Antibodies from patient serum, be it immunoglobulin (Ig)M, long after convalescence, or against heterotypic stains, were able to neutralize HEV in cell culture, demonstrating the validity and utility of the system.

Currently no information is available regarding the viral receptor for HEV. However, progress has been made to demonstrate that HEV VLPs enter the cell via clathrin-mediated endocytosis.[78] After the virus gains access to the cell, it uncoats and translates its RNA to produce enough nonstructural proteins to begin the transcription and replication process.[121] A genomic and 2-kb subgenomic RNA are produced, as well as a negative strand replication template.[53,151] Studies using real-time PCR coupled with live cell imaging demonstrated a peak of negative-strand RNA at 8 hours after infection, followed by a decline.[170] Positive strand RNA peaked at 14 hours after infection. With the accumulation of transcripts, structural proteins begin to accumulate, as well as more plus sense daughter RNA. ORF2 gets cleaved, dimerizes, and associates with the HEV RNA to form new virions.[146] These accumulated virions are subsequently released by an unknown mechanism.

Viral Genetics

HEV has four main genotypes.[174] Genotype 1 is distributed throughout the world from South Asia to Northern Africa. Genotype 2 is most common in Mexico but has been isolated in certain countries in Africa. Genotypes 3 and 4 are the zoonotic strains of HEV that are found in swine and humans from developed Western countries and China, respectively. Genotypes 1 and 2 are approximately 70 to 80 percent homologous, and genotype 3 strains are more removed from genotype 2 strains (25% to 50% homology).[109] Generally, genotypes 1 and 2 are closer to each other and genotypes 3 and 4 are closer to each other.[99] This makes sense because genotypes 1 and 2 are responsible for endemic and epidemic diseases and genotypes 3 and 4 are responsible for zoonotic disease and sporadic human cases.

There is only one serotype of HEV.[107,110,136,174] There is some evidence that HEV develops quasi-species during epidemics that allow for adaptation within individual hosts.[54]

Taxonomy and Classification

Before the characterization of HEV, it was proposed to be closely aligned with the Calicivirus family based on physical characteristics.[18,149] After the full cloning of the virus and the identification of the three ORFs, the virus was formally classified with the Caliciviruses.

Subsequent work showed that HEV shared several characteristics with rubella virus and other "alpha-like" viruses.[89] An analysis performed comparing the helicase and polymerase regions of HEV with members from the Caliciviridae, Picornaviridae, and Togoviridae families showed significant divergence.[22] The International Committee on Taxonomy of Viruses decided to separate HEV from the Caliciviridae family based on these findings and leave it unclassified, where it still remains.[55]

EPIDEMIOLOGY

Endemic Hepatitis E Virus

HEV is endemic in areas of the developing world where sanitation and clean water are not readily available. South and Southeast Asia and North Africa experience endemic disease, as well as regions of Mexico and South America. Large epidemics of HEV infection occur in these endemic countries related to widespread contamination of water after natural disasters. Cases of HEV infection outside these areas were inevitably traced back to some travel to one of these areas. Global estimates of the burden of HEV infection in endemic countries arrived at 20 million incident infections in 2005, with over 3 million symptomatic cases and 70,000 deaths.[131] Sixty percent of these cases occur in South and East Asia, with another 14 percent in North Africa.

Most of the seroprevalence studies performed in endemic countries have shown that unlike in HAV infection, children are not universally infected with HEV early in life. Children in the first decade have anti-HEV–positive rates of approximately 3 to 4 percent,[12,15] and the peak of HEV seropositivity is the second and third decades of life. However, studies from regions of Egypt and northern regions of India demonstrate a pattern that is similar to that of HAV, with 60 to 70 percent of children under 10 years being anti-HEV–positive.[6,47,106] Egypt has much higher prevalence than neighboring Israel, and southern and central India have anti-HEV rates much lower than those of the northern regions described above.[12,80,113] A study of children from Moscow had HEV seroprevalence rates that between those of most other studies.[1] Explanations for these regional differences are lacking. Table 169-1 is a summary of HEV

seroprevalence studies performed in children from different parts of the world.*

One of the Egypt seroprevalence studies performed a follow-up study to examine seroconversion and estimated the incidence of HEV infection.[144] Of the 919 villagers who were anti-HEV–negative at the beginning of the study, 34 seroconverted over 10 months, or an incidence of 41.6/1000 person-years for this group.

Studies of sporadic acute hepatitis in endemic areas indicate the burden of HEV disease in those countries. Studies examining children with acute hepatitis symptoms in Egypt and Sudan show that HEV infection is either the leading cause or second leading cause in children.[42,66,67] A similar study from India showed that although HEV infection was the second leading cause after HAV infection of acute hepatitis requiring admission to a children's hospital, it caused a slightly higher percentage of acute liver failure.[125] One study found that HAV and HEV infections led to worse outcomes in acute liver failure, but others have not substantiated those findings.[16,102]

Several studies from endemic areas were specifically designed to examine the differences between HAV and HEV infections.[29,135] The results of these studies have shown that HAV disease peaks earlier in life than HEV disease and that although the clinical symptoms of acute hepatitis are very similar, the hepatic dysfunction from HEV infection tends to peak earlier in the illness and may take longer to resolve. Because the peaks of HAV and HEV seroprevalence and disease in endemic countries do not overlap, this has led some to think that HAV disease somehow protects against or interferes with HEV infection.[147] No specific proof of this hypothesis is available currently.

Although the reservoir for HEV is not known, the detection of HEV from various sewage samples combined with patients with prolonged viremia make it likely that the virus can exist in these environments to sustain its transmission cycle.[118,124,169]

Epidemic Hepatitis E Virus

HEV epidemics are often related to events that cause disruption of sanitary conditions (e.g., war, earthquakes, and flooding). Recent war-associated epidemics among the refugees from the Darfur region of Sudan and Iraq in 2004 illustrate the nature of HEV epidemic circulation.[24,51,57,173]

In a refugee camp in Western Sudan, more than 2600 cases of HEV infection were reported among the estimated 78,000 residents in the second half of 2004.[24,57] Of the total cases, almost 10 percent required hospitalization, and of the hospitalized patients, 45 (17.8%) died.[24] The bulk of the mortality was in the pregnant women—19/45 (42.2%); in fact, the sentinel cases for the HEV infection epidemic were 2 pregnant women who died in July 2004. The overall mortality rate for the epidemic was 1.7 percent. Of the 1133 pregnant women in the refugee camp, 220 reported jaundice (19.4% attack rate) and the mortality rate was 8.2 percent

The main source of water for the camp was unchlorinated groundwater pumped in through pipelines or surface water with chlorine added that refugees could access.[57] In the analysis of those patients with symptomatic HEV infection and those with asymptomatic infection, patients aged 15 to 45 years had a higher attack rate and more symptomatic infections (4.3% and 71%, respectively) in contrast to the group younger than 15 years of age (2.4% and 22%, respectively). Intrafamilial spread of HEV previously did not appear to play a significant role during epidemic conditions.[4,14] However, a large outbreak in northern Uganda with over 3000 cases demonstrated in households with two or more cases that they were more likely to have had contact with people likely to have been infected with HEV.[156] All tested water and zoonotic sources were negative for HEV, thus suggesting person-to-person spread.

Zoonotic Hepatitis E Virus

As more widespread serologic studies were performed to assess rates of anti-HEV seropositivity, cases with no identifiable travel risks were discovered in developed countries with no known endemic HEV activity.[50,104,158] Many of the cases had heavy animal exposures, most commonly to swine. This led researchers to investigate the possibility that HEV was in fact a zoonosis and that either direct animal contact or ingestion of raw or undercooked meat could produce HEV infection. Meng and associates[111] conducted a multiphase study to determine if swine were infected with HEV and to isolate the virus.[111] They performed enzyme-linked immunosorbent assays (ELISAs) on multiple swine herds and found the majority to be anti-HEV–positive and that the seroprevalence increased with age. They followed newborn piglets, monitored for seroconversion, and demonstrated concurrent histologic hepatitis and viremia by RT-PCR. In a follow-up study, serum from the infected piglets was used to successfully infect pathogen-free experimental pigs.[108] Pigs could not be infected with human strains of HEV. Rhesus monkeys and chimpanzees, a human surrogate, were successfully infected with the swine HEV.[109] An isolate of HEV from the United States that was genetically similar to the swine HEV successfully infected pathogen-free pigs, thus proving that swine HEV could infect both pigs and humans and was the likely cause of sporadic cases of HEV in the United States and other developed countries. It has now been established that HEV genotypes 3 and 4 are the strains most frequently isolated from animals that are found in nonendemic HEV infection cases from industrialized countries.[36]

Many animal species are likely infected with HEV. Among those described are swine, deer, chickens, rodents, and cats.[62-64,72,119] Of note, avian HEV, which has been demonstrated as the cause of hepatosplenomegaly syndrome in chickens, shares only 50 to 60 percent homology with human and swine HEV and has not been shown to be able to infect nonhuman primates.[63,65]

Vertical and Breast Milk Transmission

Studies done on pregnant women with HEV have shown that vertical transmission does occur. The small studies performed show that HEV is likely transmitted at high rates, and the infants can be severely affected or suffer fetal demise before or soon after birth.[85,86,140]

Limited studies have been conducted on breast milk transmission. HEV RNA and anti-HEV antibody have been detected in colostrum components, but at significantly lower titers in contrast to serum.[31] No cases of HEV transmission in the infants were definitively linked to breast milk; however, the mothers with advanced liver disease were not allowed or able to breast-feed in this study. In short, no recommendations exist to contraindicate breast-feeding in this population aside from those mothers with severe disease.

Other Modes of Hepatitis E Virus Transmission

Cases have been reported of HEV linked with transfusion of contaminated blood. Donors were in the presymptomatic viremic phase and recipients of those blood products developed symptoms of acute hepatitis with a shorter incubation period than patients infected via the usual fecal-oral route.[10,11,25,87]

Consumption of undercooked wild game meat has been implicated in HEV infections. Several cases have been reported of acute HEV infection after consumption of uncooked or undercooked deer and wild boar meat.[93,154,155] An outbreak in France was traced to consumption of uncooked pig liver sausage.[35] Comparison of HEV RNA sequences from index cases and sausages revealed 99.4 percent identity, leading to a new package label recommending the sausage be cooked before eating.

PATHOGENESIS AND IMMUNITY

Pathogenesis

The details of pathogenesis in HEV infection are largely unknown. After an individual consumes HEV-contaminated water or food, it is unknown how the virus infects enterocytes and spreads from the intestine to the liver. Studies in swine show replicative HEV RNA present in colon, small intestine, lymph nodes, tonsils, and liver as early at 3 days after infection.[171]

Evidence of HEV replication within the liver as detected by HEV antigen is apparent by 7 days after infection. At its peak, HEV antigens can be detected in 70 to 90 percent of hepatocytes before the onset of symptoms and then drops off rapidly.[3] Viremia is detectable in serum, stool, and bile before the onset of symptoms.[30,98,160] Anti-HEV appears at the same time as the histologic signs of inflammation.[33] Similar to HAV infection, disease is likely caused by the immune response to the virus and not the virus itself.[3]

The majority of the information regarding progression and pathogenesis come from HEV inoculation of animals.[18,98,160,163] These studies usually involved intravenous administration, with an incubation period from administration to viremia of approximately 3 weeks, approximately 1 week less on average than humans. HEV RNA can be detected in serum, stool, and bile 1 week before clinical symptoms become apparent.

In the HEV infection volunteer studies, the patients developed constitutional symptoms at approximately 4 weeks after administration.[18,30] Specific symptoms and the biochemical abnormalities of hepatitis developed 1 week later. Early studies showed viral particles appeared in stool with the onset of symptoms and continued through the peak hepatitis symptoms and antibody was present at the only time they tested, 1 week after the peak hepatitis symptoms.[18] Subsequent studies using RT-PCR showed HEV RNA was present in serum before stool samples, and was present from 1 week before to 2 weeks after symptoms had begun.[30] Peak alanine aminotransferase elevations corresponded with peak symptoms, and symptoms lasted between 30 and 80 days. HEV IgG persisted well beyond the study end point.[30]

The presence of HEV RNA in stool and serum can vary significantly from patient to patient.[5] In 20 patients diagnosed with sporadic HEV infection, HEV RNA appeared in serum at days 4 to 7 after the onset of symptoms in 89 percent of patients tested and persisted beyond day 22 in 21 percent. HEV RNA in stool samples was present in 73 percent of patients at days 8 to 14 after symptoms, peaking slightly later than serum HEV RNA, and persisted beyond day 22 in 13 percent. A subset of patients will have HEV RNA in serum and stool for up to 120 days.[118] It is possible that these patients with prolonged shedding may serve as a reservoir for spread of HEV to the environment.

A summary of the clinical progression of HEV infection is graphically represented in Figure 169-2.

Immunity

HEV antibody appears with the onset of symptoms and after the peak of viremia. IgM appears just ahead of IgG (Fig. 169-3). HEV IgA appears at the same time as IgM and appears to persist slightly about 1 month longer after infection than IgM.[148,159] ORF2 is the dominant immunogen across all types of HEV infection, although antibodies to ORF3 can be detected in patients.[56,66,67,104,178] A more detailed discussion of neutralizing antibodies can be found in the discussion of vaccines.

Some studies of patients after infection have shown HEV IgG responses wane quickly after infection, whereas others show a more durable antibody response.[52] The waning of IgG levels forms the basis for the theory that susceptible adults are the vulnerable population during HEV outbreaks.

Cellular immunity to HEV plays a role in eradiation of infection and persistence of viral immunity.[117] Specific studies comparing patients with resolved acute HEV and transplant patients with resolved and chronic HEV infection have demonstrated a role for broad polyspecific T-cell responses against the virus.[145] Regulatory T cells appear to increase in number during acute HEV infection.[161]

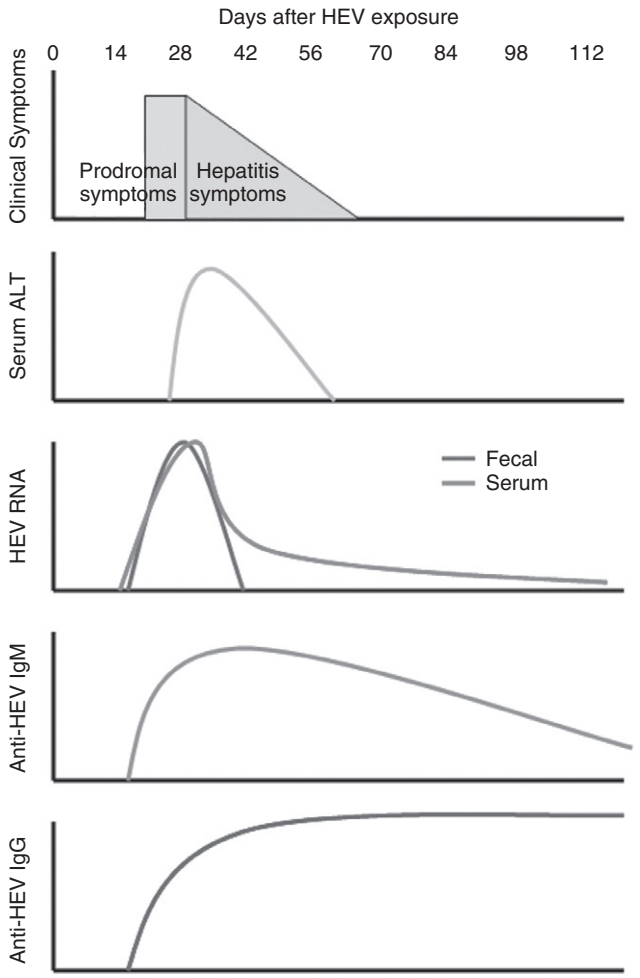

FIGURE 169-2 ■ Representation of the course of hepatitis E virus (HEV) infection with approximate times after HEV exposure. In volunteer and animal experiments, prodromal symptoms will appear approximately 3 weeks after infection, which precedes the symptoms of hepatitis by about 1 week. The hepatitis symptoms can last 4 to 6 weeks on average, with significant variation. Serum alanine aminotransferase peaks with the onset of hepatitis symptoms. HEV RNA can be detected in either stool or serum approximately 3 weeks after infection with the onset of the prodrome and can be detected for 1 to 3 weeks in duration, with some patients experiencing prolonged viremia. HEV immunoglobulin (Ig)M and IgG appear in concert with the onset of symptoms and after the peak of HEV RNA. IgM peaks slightly earlier than IgG and can taper quickly, with some disappearing by 3 months. IgG peaks later and lasts several months after infection.

CLINICAL MANIFESTATIONS

The signs and symptoms of acute HEV infection are indistinguishable from those seen with HAV infection.[3,29,67,135] A prodromal illness consisting of malaise, anorexia, nausea, abdominal pain, fever, myalgia, and headache precedes the findings of jaundice, hepatomegaly, and serum transaminase elevations.

One study examining children after a common source exposure provides insight into the manifestations of HEV infection in this group. Twenty students from a private school in urban North India were exposed to HEV while on a camping trip.[17] The exact source was never identified, but investigators were able to monitor the children for signs and symptoms of HEV infection and serologic and virologic confirmation of infection. The clinical symptoms are summarized in Figure 169-3. Of the 20 children, 17 developed clinical illness (85%) but only 10 developed symptoms of acute hepatitis. The other 7 remained anicteric, with symptoms of malaise, nausea, abdominal pain, and headache. The children with jaundice had a different incubation period (25 to 38 days, median 33 days) in contrast to the children without jaundice (22 to 95 days, median 27 days). HEV IgM was found in all patients. HEV RNA was found in 11 children, including one of the children who never developed symptoms. Because this study is one of the few to have a point source of exposure, it is difficult to know if the very high rate of infection is due to the younger age of the patients, the strain of the virus, or the nature of the exposure.

Rates of fulminant hepatic failure and mortality from HEV infection are estimated to be approximately 1 to 4 percent. Studies from endemic areas suggest that the rate may be higher in children, but those data have not been widely substantiated.[126] The rate is closer to 15 to 50 percent in patients with preexisting liver diseases and compensated cirrhosis, whether due to chronic hepatitis B or C or other metabolic liver disease.[130]

It was previously thought that HEV caused only acute disease; however, recent studies demonstrated that chronic HEV infection can occur in immunocompromised and transplant patients.[59,75] This has been observed in children, with outcomes including cirrhosis and death.[60,61]

Pregnant women are highly vulnerable to HEV infection.[37,84] It was recognized before HEV was fully characterized that infected pregnant women had high rates of fulminant liver failure and mortality rates of 20 percent or higher.[88] One study from India of pregnant women with acute hepatitis demonstrated not only that HEV caused fulminant hepatitis and death more frequently, but it was also associated with many obstetric complications (i.e., antepartum and postpartum hemorrhage, premature rupture of membranes, and intrauterine fetal death) and poor fetal outcomes (i.e., preterm delivery and stillbirths) in contrast to other forms of viral hepatitis.[123] This feature of HEV is not restricted to a particular region or genotype, as illustrated by the Darfur outbreaks. The mechanism for severe disease in these women is unknown, although one study showed an increased Th2 cytokine bias in peripheral blood morphonuclear cells from pregnant HEV-infected patients that could allow for a dysregulated inflammatory response.[24,120] Pregnant women with HEV infection have significantly longer periods of viremia than nonpregnant counterparts, also supporting the idea of a muted or dysfunctional immune response.[21]

Extrahepatic manifestations of HEV infection have been reported, but they are uncommon. Pancreatitis can occur shortly after the onset of acute hepatitis symptoms.[70,101,112] Several reports have described patients with significant hemolysis with glucose-6-phosphate dehydrogenase (G6PD) deficiency associated with acute HEV

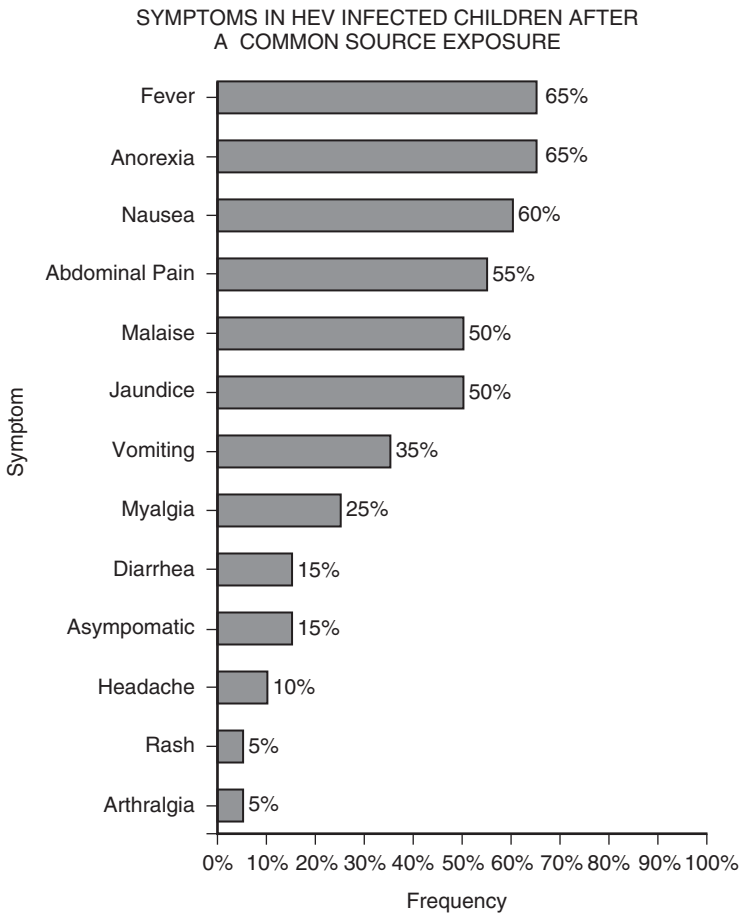

FIGURE 169-3 ■ Symptoms observed in children after a common-source exposure to hepatitis E virus. Jaundice was seen in only 50 percent of patients overall, and 15 percent were completely asymptomatic. (From Arora NK, Panda SK, Nanda SK, et al. Hepatitis E infection in children: study of an outbreak. *J Gastroenterol Hepatol* 1999;**14**: 572-577.)

infection.[2,180] Neurologic manifestations described include transverse myelitis, Bell palsy, and Guillain-Barré syndrome.[39,40,74,103,141] All of these manifestations resolve spontaneously in conjunction with the hepatitis. It is not clear whether these are a result of direct viral effects or an immune-mediated phenomenon. It is interesting that most of the extrahepatic manifestations have been reported in children.

DIAGNOSTIC TESTING

Serology

Antibody confirmation is the most widely available method used to diagnose HEV infection. ELISA for both IgG and IgM can be performed at many reference laboratories. The ORF2 capsid protein is the most common antigen used to detect antibody.[164] Some studies have shown that inclusion of the other ORFs can increase the specificity and positive predictive value of the test. A few studies indicate that HEV IgA may perform better than IgM based testing.[148,159] This needs to be confirmed in larger studies.

A comparison of various HEV ELISA kits during an epidemic in Indonesia found that the sensitivity of the tests was much better in symptomatic patients than in asymptomatic ones (72% to 91% vs. 39% to 51%, respectively).[114] Also, the Walter Reed kits for IgG and IgM performed better than the GeneLabs and Abbott IgG tests. Testing of normal healthy controls that were HEV PCR–negative showed that the serologic testing had high specificity, again with the Walter Reed tests performing best. The caveat of the study is that the GeneLabs IgM kit was an older version of the test, and the limitations of the assay may not apply to the newer kit.

A new rapid immunochromatographic assay showed promising results when it was evaluated for use in resource-poor countries to diagnose acute HEV infection.[115] Using 25 μL of serum or 35 μL of whole blood applied to the test strip and a 15-minute incubation period, the kit had a sensitivity of 93 percent and a specificity of 99.7 percent.

Polymerase Chain Reaction

RT-PCR for HEV RNA can be performed within the first month of illness on either serum or stool.[5] The testing is less commercially available and likely conducted in research or select public health laboratories. Several recent studies have shown that real-time PCR testing may allow more rapid and sensitive detection of HEV RNA, with the additional benefits of detecting multiple HEV genotypes and the ability to test environmental samples in addition to clinical samples.[46,71]

Electron Microscopy

HEV has also been visualized in stool samples from patients using electron microscopy.[18,142] In general, these methods incorporate HEV antibody to adsorb intact virus to increase the likelihood of detection. Again, this testing is not generally available.

PREVENTION AND VACCINE CANDIDATES

Disease Avoidance

Practical measures can be taken to reduce the risk for HEV infection when traveling to endemic regions.[28] Consumption of only boiled or bottled water, avoidance of ice, eating fruits that can be peeled, and eating only well-cooked foods are all recommended measures.

Specific consideration should be made for pregnant women and patients with chronic liver disease to avoid travel to areas endemic for HEV or regions experiencing HEV infection outbreaks.

Antibody Preparations

No antibody preparations are available that can be used as preexposure or postexposure prophylaxis for HEV infection. Small studies have shown successful passive immunization in animals.[165] Some studies have used immune serum globulin in endemic areas with mixed effects.[13,84] These studies are all small, and the antibody preparations were of varying amounts and given at varying times, so definitive conclusions about the role of antibody cannot be made.

Therapies

Most patients do not need therapy for HEV infection. However, patients with less common manifestations might benefit if therapies existed. Ribavirin has been used with success in patients with fulminant infection, although it is not clear whether the drug was critical in the recovery of the patient.[49] For immunocompromised patients with chronic HEV infection, several anecdotal studies have examined using pegylated interferon–α for 3 to 6 months in duration with high rates (60% to 80%) of resolution of HEV viremia and only a few reported relapses.[58,76]

Few studies have examined therapeutic options for acute HEV infection. One uncontrolled study used glycyrrhizin in patients with significant acute hepatitis from HEV infection, but no meaningful conclusions can be drawn from its results.[153] A hammerhead ribozyme targeted to the 3′ UTR have shown decreases in the in vitro activity of an HEV reporter.[143] Development of therapies for HEV infection is not likely to be effective for the simple reason that the peak of viral activity is usually before and along with the onset of symptoms. The patients with prolonged viremia are not necessarily the sickest patients and are often asymptomatic.

Vaccine Candidates and Future Therapies

Early vaccine studies used cynomolgus monkeys actively immunized with a recombinant ORF2 protein. Subjects were protected after challenge with homologous virus in contrast to passively immunized or control animals.[165]

Work to identify neutralizing antibody showed that the epitopes recognized were in the terminal region of ORF2, amino acids 578-607.[136] These antibodies were protective of HEV infection when incubated with HEV before administration to monkeys. This epitope is present within the 56-kDa form of the capsid protein.

A recombinant 56-kDa ORF2 vaccine protected rhesus monkeys challenged with HEV 1 month after a 2-dose series.[128,166] Repeat challenge at 6 months and 1 year showed protection against hepatitis in 75 percent, which increased to 100 percent in animals given a third dose of vaccine 1 month before challenge.[181] Postexposure vaccination did not prevent HEV infection.

Subsequent phase I testing in humans induced anti-HEV titers 40 U/mL and greater in 88 percent of vaccinees after three doses.[134] Only a few minor local reactions occurred and no significant adverse events. Based on these early trials, a large human field trial was completed in Nepal in 2001. A group of 2000 seronegative soldiers were randomized to receive three doses over 6 months of the recombinant HEV vaccine or placebo.[138] The subjects were followed for signs and symptoms of acute hepatitis for 2.5 years. The study included 69 total cases of acute HEV infection, 66 in the placebo group, and 3 in the vaccine group, with an efficacy of 95.5 percent in subjects receiving three doses of vaccine. The intent to treat analysis showed an efficacy of 88.5 percent. The vaccine was well tolerated, with local pain at the injection site being the most frequent complaint.

Another version of recombinant vaccine against hepatitis E produced in bacterial cells has moved through preclinical testing with promising results. A large phase III trial in China with more than 90,000 subjects showed the vaccine was highly protective, with rates of 95 to 100 protection.[182] Only one case of HEV infection was observed in a subject that received only 1 dose of vaccine, in contrast to 22 in the placebo group. A subsequent analysis of women in the study who became pregnant after enrollment demonstrated no associated pregnancy complications or fetal morbidity or mortality.[175] Antibody levels among those women who received study vaccine were comparable to those in nonpregnant counterparts in the study. These findings certainly raise the possibility that an HEV vaccine may become available to protect pregnant women in endemic areas.

Alternative vaccine strategies being investigated include VLPs given orally to induce local and systemic immunity. Mice immunized with HEV VLPs in increasing amounts developed serum IgG and IgM responses at 2 to 4 weeks after immunization.[92] Mice given the higher inoculums (50 and 100 μg) also developed fecal IgA responses. Subsequent challenge experiments in cynomolgus macaques showed that oral immunization with

VLPs not only produced serum and fecal antibody but protected the animals from intravenous challenge with native HEV strains.[94] DNA vaccines have shown encouraging initial results as well. Macaques given a DNA plasmid encoding for the HEV ORF2 using the gene gun technique developed significant anti-HEV IgG within 4 months of vaccination; vaccinated animals were protected against challenge with infectious HEV and control animals developed clinical disease.[77]

SUMMARY

Despite the lack of a tissue culture system for HEV, much progress has been made toward a vaccine that is effective. Fundamental questions of virus entry and pathogenesis still linger, as well as why certain patients are highly susceptible to severe HEV disease, whereas others are not. The nature of the differences in the epidemiology and clinical manifestations of HEV infection in children also needs to be studied further. Recent large-scale trials offer promise that an efficacious vaccine may be available in the near future to protect those most vulnerable to HEV infection.

RNA VIRUSES
SUBSECTION 3 *REOVIRIDAE*

CHAPTER 170

Reoviruses

James D. Cherry

Reoviruses are ubiquitous in nature, but their role in human disease is vague. After reoviruses were classified in 1959, numerous reports noted their association with human disease.[44,75,86] Since that time, these viruses have been evaluated extensively in laboratory animal studies, but few cases of human disease have been reported during the last 4 decades.

HISTORY

On the basis of its cytopathic effect in monkey kidney tissue culture and its recovery from stool specimens at a time of enterovirus surveillance, the first recovered reovirus was designated ECHO virus type 10.[12,13] This virus and four similar strains were recovered in 1954 from the stools of healthy children in Cincinnati and Mexico.[68,69] By 1959, researchers were aware that ECHO 10 viral strains appeared to have many characteristics that were different from those of enteroviruses, such as large size and unique cytopathic effect, and they were withdrawn from this grouping. The term *reovirus* was chosen to stress the association of these agents with both the respiratory *(r)* and enteric *(e)* tracts. The *o* for orphan was retained in the designation. In the early 1960s, reoviral infections were noted in association with human illness.*

PROPERTIES†

Reoviruses are members of the family *Reoviridae*.[20,58,60] This family has numerous double-stranded RNA viruses that infect mammals, birds, reptiles, fish, mollusks, insects, plants, and arthropods.[60] Nine genera are in the family, and they can be subdivided by the presence or absence of a turretlike protein that projects from the innermost capsid layer. Of the turreted *Reoviridae*, only orthoreoviruses infect humans and are addressed in this chapter. Orthoreoviruses commonly are called simply reoviruses. Nonturreted *Reoviridae* include the following viruses that cause disease in humans: rotaviruses (Chapter 172) and orbiviruses and coltiviruses (Chapter 171). Three serotypes of orthoreoviruses cause infection in humans. All mammalian reoviruses are related by a common group-specific, complement-fixing antigen.[83,104] Three distinct human serotypes can be identified by neutralization or hemagglutination inhibition.[73]

Reovirus particles are composed of an inner protein shell (core) with a diameter of 60 nm that is surrounded by an outer protein shell (outer capsid) measuring 81 nm in diameter.[60] The outer capsid has icosahedral symmetry and is composed of 92 to 180 hexagonal and pentagonal subunits (capsomers). The genome of orthoreoviruses has a total size of approximately 23,500 base pairs with 10 gene segments: three large (L1, L2, L3), three medium (M1, M2, M3), and four small (S1, S2, S3, S4). These genes encode 12 proteins. The outer capsid comprises four proteins: σ-1, σ-3, λ-2, and μ-1. The σ-1 protein is the reovirus cell-attachment protein against which serotype-specific neutralizing antibodies are developed. This protein also is the hemagglutinin. The reovirus receptor is the junctional adhesion molecule 1 (JAM1).[21,97] The σ-3 protein binds double-stranded RNA and is sensitive to protease degradation. It is a zinc metalloprotein that has effects on translation. The λ-2 protein is important in particle assembly and μ-1 in cell penetration.

The inner capsid is composed of four proteins: λ-3, λ-1, μ-2, and σ-2. The λ-3 protein is an RNA-dependent RNA polymerase. The λ-1 protein is a zinc metalloprotein that binds RNA. The μ-2 protein binds RNA, and σ-2 binds double-stranded RNA.

The four nonstructural proteins are μ-NS, μ-NSC, σ-1s, and σ-NS. The μ-NS protein is a core-binding protein, and σ-NS binds single-stranded RNA. The roles of μ-NSC and σ-1s are unknown.

Reoviruses are moderately heat-stable. The half-life at 56° C (132.8° F) of a type 3 strain is 1.6 minutes; at 37° C (98.6° F), it is approximately 2.5 hours. Reoviruses are inactivated by visible light in the presence of heterocyclic dyes. They are inactivated by ultraviolet light but are more resistant to this treatment than are RNA viruses with single-stranded nucleic acid. Reoviruses are stable through a wide pH range and also as aerosols, particularly when the relative humidity is high. They are relatively resistant to 3 percent formaldehyde solution, 1 percent hydrogen peroxide, and 1 percent phenol but are inactivated completely by 70 percent ethyl alcohol at room temperature for 1 hour. Brief exposure to 70 percent ethanol is ineffective in disinfecting reoviruses, but brief

*References 18, 31, 35, 44, 79, 80, 112.
†References 11, 59, 75, 76, 103, 105.

exposure to 95 percent ethanol or sodium hypochlorite is effective.

Reoviruses replicate with a cytopathic effect in a large number of tissue culture systems of both primate and other animal origins. For recovery from clinical material, monkey kidney tissue culture is satisfactory. Cytopathic effect is enhanced in rolled in contrast to stationary cultures.[43] Infected cells develop characteristic cytoplasmic inclusions that contain double-stranded RNA, virus-specific proteins, and complete and incomplete viral particles. All three serotypes agglutinate human erythrocytes, and this virus-cell interaction is stable in a wide temperature and pH range.

Of all viruses that naturally infect humans, reoviruses have the broadest host range. They have been recovered from natural infections in cattle, chimpanzees, monkeys, mice, dogs, turkeys, sheep, pigs, chickens, and cats.* In addition, hemagglutination-inhibiting and neutralizing antibodies to one or more of the three reoviral serotypes have been found in the serum of rabbits, horses, trout, guinea pigs, antelopes, zebras, warthogs, bats, wallabies, quokkas, kangaroos, and several genera of New World monkeys.†

Because of their widespread prevalence in nature and the ease of causing infection in laboratory animals, reoviruses have been used widely in pathogenicity studies. The following unique illnesses have been observed: diabetes mellitus in mice; hydrocephalus in hamsters, ferrets, rats, and mice; encephalitis in mice; chronic infection with runting in mice; myocarditis in mice; chronic obstructive jaundice associated with choledochal obliteration in mice; and lymphomas in mice with chronic infection.‡

EPIDEMIOLOGY

The serologic data presented in the preceding section of this chapter demonstrate that reoviruses are prevalent infectious agents in the animal world. Similarly, surveys of sera collected from humans indicate worldwide human infection.§ The occurrence in nature of identical viruses in many different animals and humans leads to consideration of possible transmission from species to species. At present, this transmission has not been demonstrated. However, Chua and associates[8-10] present data suggesting that human reoviruses associated with respiratory infections were probably of bat origin. In addition, Ouattara and colleagues[64] have noted a reovirus type 2 swine reovirus reassortant associated with encephalitis.

Reoviruses are recovered frequently from sewage.¶ In San Diego, reoviruses have been recovered more consistently than has any other virus throughout the year from sewage.[17] This finding suggests that reoviral infection is endemic in humans in the San Diego area.

From Lerner AM, Cherry JD, Klein JO, et al. Infections with reoviruses. *N Engl J Med* 1962;**267**:947-952. Reprinted with permission from *The New England Journal of Medicine*.

The type 2 hemagglutination-inhibiting antibody prevalence pattern by age in sera collected in Boston from 1959 to 1962 is presented in Table 170-1. Antibody is transmitted transplacentally to the newborn. During the first year of life, this acquired antibody wanes, after which antibody prevalence increases with increasing age. Approximately 50 percent of school-aged children have hemagglutination-inhibiting antibody titers to type 2 reovirus of 1:20 or greater; approximately 80 percent of adults have similar titers. Two more recent studies have shown a similar prevalence of antibody to reovirus type 3.[87,98]

The method of transmission of reoviruses is unknown. However, because they are recovered most frequently from the feces, the primary spread probably is by the fecal-oral route, similar to that of enteroviruses. Because the reoviruses are stable in aerosols and because respiratory illness has been associated with reovirus infections, the respiratory route is an additional possibility.

CLINICAL MANIFESTATIONS

The role of reoviral infections in human disease is far from clear. In most instances, virologic or serologic evidence of reoviral infection has been a sporadic finding in human illness, so that cause and effect are difficult to establish. However, in volunteer studies in young adults, infection resulted in clinical illness.[31,78]

The prevalence of antibody to all three reoviral types in humans and the frequency of reovirus isolation from human sewage indicate that human infection is a common occurrence, but the relative paucity of virus recovered during studies of community disease suggests that most infections are inapparent or associated with trivial illness.

Upper Respiratory Tract Illness

In the winter of 1957, Rosen and colleagues[79] noted an outbreak of infection with reovirus type 1 in nursery children in a welfare institution. Illness was noted in

16/22 infected children and was characterized by low-grade fever (rectal temperatures from 38.1° to 38.6°C [100.6°F to 101.5°F]), rhinorrhea, and pharyngitis. The average duration of fever was 2.2 days; in 9 children, the duration was only 1 day. Three children had diarrhea, and 3 had mild otitis media. In another study conducted at the same institution during the winter of 1955 to 1956, 4 children with reovirus type 3 infection and illness were noted.[80] One child had a temperature of 38.9°C (102°F), coryza, and tonsillitis; another child had fever (temperature of 38.2°C [100.8°F]), cough, and diarrhea; and 2 children had only coryza. During another reovirus type 3 outbreak in the fall of 1957, all 6 infected infants had symptoms. Five children had mild fever, 5 had coryza, and 4 had diarrhea. Pharyngitis was not observed in any of the infected children.

Other sporadic instances of similar mild upper respiratory tract illnesses have been described.[15,27,31,90,91] In volunteer trials in young adults, reovirus type 1 infection was associated with malaise, rhinorrhea, cough, sneezing, pharyngitis, and headache in some subjects in one study,[78] and coldlike illness was observed in 37 percent of subjects in another trial.[31] In both volunteer studies and natural infection, mild diarrhea occurred with the upper respiratory tract illness.

In three separate investigations, Chua and coworkers[8-10] noted acute influenza-like illnesses in four adult patients. The reoviruses in these four cases may have been of bat origin, and in one instance evidence of human-to-human transmission was found.

Pneumonia

Tillotson and Lerner[101] described a 5-year-old girl who had extensive pneumonia and died after 15 days of illness. This child initially had fever, cough, rhinorrhea, and a generalized maculopapular rash. When admitted to the hospital on the 10th day of illness, the child was cyanotic and in marked respiratory distress; rash was no longer present, but mild pharyngitis and conjunctivitis were. A chest radiograph revealed diffuse confluent pneumonia, and reovirus type 3 was recovered from the lungs, adrenals, liver, spleen, kidney, a lymph node, heart, brain, and blood.

Joske and associates[35] described a 10-month-old girl who died after having a respiratory illness of 4 days' duration. A reovirus type 1 was recovered from the stool and brain of this child, and postmortem study revealed interstitial pneumonia, myocarditis, hepatitis, and encephalitis. El-Rai and Evans[18] reported the case of an 18-year-old man who had fever (temperature of 39.4°C [103°F]), nausea, vomiting, cough, and patchy pneumonia. He had serologic evidence of infection with reovirus type 1. Pneumonia has been noted in another child with reovirus type 3 infection.[90]

Gastrointestinal Manifestations

Mild diarrhea has been noted both in association with upper respiratory tract illness and as an isolated event.[70,78-80,82] Because reovirus type 3 consistently produces steatorrhea in mice, this clinical manifestation has been sought in illnesses of children and noted in six.[34,84] Three patients with hepatitis and encephalitis have been described.[35] Zalan and associates[112] have noted two patients in whom abdominal pain and cramps were prominent.

In 1980, Bangaru and associates[1] reported the similarity of induced hepatobiliary injury caused by reovirus type 3 infection in mice and biliary atresia in human infants. Subsequent to this observation, Glaser and associates[23] and Morecki and colleagues[55,56] looked for an association between reovirus type 3 infection and biliary atresia in humans. In their first report, they found that 17/25 patients (68%) with biliary atresia had antibodies (indirect immunofluorescent antibody technique) to reovirus type 3, whereas similar antibodies were recovered in only 3/37 control sera.[55] In a second study, they found that 62 percent of babies with extrahepatic biliary atresia and 52 percent of infants with idiopathic neonatal hepatitis had antibodies to reovirus type 3; only 12 percent of control children had similar antibodies.[23] In an ultrastructural and immunocytochemical study, they found evidence of reovirus type 3 in the porta hepatis of an infant with extrahepatic biliary atresia.[56]

Using similar serologic techniques, Dussaix and associates[16] were unable to find any relationship between reovirus type 3 antibody and either biliary atresia or neonatal hepatitis. They found reovirus type 3 antibody in sera from 45 percent of infants with biliary atresia, 50 percent of infants with neonatal hepatitis, and 50 percent of control infants. Minuk and colleagues[54] found no association between reovirus type 3 infection and idiopathic cholestatic liver disease in adults. Brown and colleagues[7] reported a relatively large study of reovirus type 3 infection and extrahepatic biliary atresia and neonatal hepatitis. They interpreted their data as demonstrating no correlation between the virus and the illnesses studied. However, the geometric mean antibody value in the combined biliary atresia and neonatal hepatitis groups was significantly higher than that of the control group. Richardson and associates[72] reported a study in which they examined the percentage of immunoglobulin (Ig)G, IgA, and IgM serum antibodies to reovirus type 3 in 40 infants with extrahepatic biliary atresia, 59 infants with neonatal hepatitis, 61 infants with cholestatic liver disease with causes other than extrahepatic biliary atresia or neonatal hepatitis, and 138 control infants with no liver disease. They found no difference in the prevalence of IgG and IgA antibodies between the groups with liver disease and the control subjects. They did, however, note a greater prevalence of IgM antibody in each of the groups with liver disease in contrast to the rate in the control group. However, this increased prevalence of IgM antibody could be the result of false-positive titers as a result of the liver disease rather than evidence of recent or ongoing infection. Steele and associates,[96] using a reverse transcriptase–mediated polymerase chain reaction (RT-PCR), found no evidence of reovirus type 3 in preserved tissues from infants with cholestatic liver disease. Saito and associates,[83] using RT-PCR, could find no amplification product in tissue or stool specimens from patients with biliary atresia, infantile obstructive cholangiopathy, or congenital dilation of the bile duct.

In 2009, Rauschenfels and colleagues[71] did an extensive study on the incidence of hepatotropic viruses in

biliary atresia. They obtained liver biopsies from 64 infants with biliary atresia at the time of the Kasai procedure. They identified reovirus type 3 RNA by RT-PCR in 21 (33%) biopsies. They noted that the 21 patients who were reovirus-positive were older (mean age, 60 days) than those who were virus-negative (mean age, 54 days). This finding led them to suggest that the viral infection was a secondary phenomenon and not the cause of the biliary atresia.

Exanthem

Exanthem has been a common manifestation of clinically apparent reoviral infections.[18,35,44,101] Lerner and associates[44] noted exanthem in six of seven children infected with reovirus type 2. Predominant symptoms in these patients included fever, malaise, anorexia, and pharyngitis. Two children had adenopathy, and one child had diarrhea. The rash was maculopapular in five patients and vesicular in one child. One child had a measleslike illness with photophobia, conjunctivitis, cervical lymphadenopathy, and a confluent maculopapular rash that lasted approximately 1 week.

Exanthem has been noted in a 5-year-old girl with pneumonia and type 3 reovirus infection, a 28-month-old girl with encephalitis and type 2 infection, and an 18-year-old adolescent male with pharyngitis and cervical and posterior occipital lymph node enlargement and type 2 infection.[18,35,101]

Neurologic Disease

Joske and colleagues[35] described three cases of hepatitis-encephalitis syndrome with reoviral infections. All of these cases had abnormal liver function test results and clinical and laboratory evidence of meningeal and cerebral involvement. One child died, one had mild neurologic residua at the 6-week follow-up, and one recovered without difficulty. Two patients were infected with reovirus type 2 and one with reovirus type 3.

El-Rai and Evans[18] found serologic evidence of reovirus type 2 infection in two children with aseptic meningitis, and Zalan and colleagues[112] described two children with reovirus type 2 infections associated with leg weakness and pain. Johansson and colleagues[33] noted a 3-month-old girl with meningitis, diarrhea, vomiting, and fever. Reovirus type 1 was isolated from this child's cerebrospinal fluid (CSF), and the child had a fourfold rise in neutralizing antibody to the isolated virus. Krainer and Aronson[40] described a 29-year-old woman who died of disseminated demyelinating encephalomyelitis in which a reovirus was recovered from the CSF and brain. Tyler and associates[106] isolated a type 3 reovirus from the CSF of a 6.5-week-old child with meningitis. This child recovered without obvious neurologic sequelae.

Ouattara and associates[64] reported a 6-year-old boy and his 2-month-old girl cousin with acute encephalitis associated with a reovirus type 2 infection. The boy had a febrile prodrome and then vomiting and impaired consciousness. On examination, he had a palsy of the left facial nerve. His CSF had a mildly elevated protein without pleocytosis. Magnetic resonance imaging (MRI) showed multiple symmetric lesions. He recovered completely in a few weeks. The cousin had fever, asthenia, and rhinorrhea. She also had a mildly elevated CSF protein and MRI findings similar to those of her older cousin. At hospital discharge at 18 days, she had marked hypotonia and the absence of language. At 1 year follow-up, she had uncoordinated movements. A similar virus was isolated from the urine of both children. This virus was thought to be a reassortant between human and swine strains. Krainer and Aronson reported a 29-year-old woman who died of a disseminated demyelinating encephalomyelitis in which a reovirus was recovered from the cerebrospinal fluid and brain.[41]

Other Manifestations

A 25-year-old man with Hodgkin disease had persistent reovirus type 1 viruria for a 5-week period, but no associated clinical illness was demonstrated.[17] Reoviruses have been recovered from biopsy material from patients with Burkitt lymphoma.[2,3] One child with hemorrhagic bullous myringitis was infected with reovirus type 2.[112] Terheggen and colleagues[100] noted a 28-year-old man with mild myocarditis from whom a reovirus was isolated from the stool sample.

REOVIRUSES AS POTENTIAL ANTI-CANCER AGENTS

Studies during the present decade indicate the potential of reoviruses to selectively destroy many different types of neoplastic cells.* Many malignant cells have an activated Ras pathway that results in a deficient ability to mount an antireovirus response that is mediated by the cellular protein PKR. Organ culture and animal model systems have shown promising results with reovirus type 3 in numerous different malignant neoplasms. At present, many phase I and phase II trials are in progress.[25,65,107]

DIAGNOSIS

Because no specific clinical features suggest reoviral infection, virologic and serologic studies are necessary for establishing the diagnosis. Reoviruses can be recovered from clinical material in primary monkey kidney tissue culture.[76] Care must be taken in interpreting results, however, because reoviruses can be contaminants of monkey tissue cultures. Cytopathic effect in tissue culture is enhanced by rolling during incubation.[43] Identification of virus is made by neutralization; the distinctive cytopathic effect should be helpful in selecting strains for study with reovirus antisera. In research laboratories, reoviruses also can be detected by molecular techniques such as in situ and dot-blot hybridization and PCR.[71,104] Paired serum specimens can be examined for antibody titer rise to reoviruses by neutralization, indirect immunofluorescent antibody technique, enzyme-linked immunosorbent assay (ELISA), or hemagglutination inhibition.

*References 10, 17, 19, 23, 24, 28, 29, 36, 38, 52, 53, 89, 106, 110, 111.

Recent infection can also be identified by the demonstration of specific IgM antibody by ELISA.

CHAPTER 171

Orbiviruses, Coltiviruses, and Seadornaviruses

Theodore F. Tsai

Viruses in the genera *Orbivirus*, *Coltivirus*, and *Seadornavirus* differ from others in the family *Reoviridae* structurally, in physicochemical properties, and by their arthropod mode of transmission.[2,3] More than 100 orbiviruses are classified into serogroups by relationships in complement fixation, agar gel precipitation, and immunofluorescent assays. Additional serocomplex relationships are recognized, whereas individual viruses are differentiated by neutralization tests. Orbiviruses are principally animal pathogens (e.g., the bluetongue viruses); only viruses in the Kemerovo, Orungo, Lebombo, and Changuinola serogroups have been shown to cause human illness. Colorado tick fever (CTF) virus is the only *Coltivirus* recognized to cause human illness, and among the seadnornaviruses, only Banna virus is a confirmed human pathogen.[2,3]

The orbiviruses are spherical nonenveloped viruses with two protein shells: an outer shell (capsid) approximately 86 nm in diameter and an inner shell (core) 69 nm in diameter. The inner core VP7 protein, arranged in trimers, contains group-reactive antigens, and the outer capsid VP2 or VP5 proteins bear serotype-specific antigens. The viruses are acid labile, and some exhibit sensitivity to lipid solvents. The double-stranded RNA viral genome comprises 10 segments associated with viral structural and nonstructural proteins. Their complete nucleotide sequences and coding assignments have been determined for a bluetongue virus, and partial information is available for others. In general, reassortments of genomic segments among viruses within serogroups are viable, but not between groups, thus validating the broad serogroup classification. The genetic relationships (e.g., RNA hybridization) among viruses within serogroups diverge from the antigenic relationships in some instances, which provides an additional basis for taxonomic classification.

The coltiviruses and seadornaviruses resemble the orbiviruses in size and in having two capsids but possess genomes organized into 12 RNA segments.[2] Seadornaviruses' morphologic features and structural protein similarities with rotaviruses suggest an evolutionary relationship.[36]

COLORADO TICK FEVER VIRUS

CTF is an acute tick-borne febrile illness caused by the eponymous *Coltivirus*.[5,13,18,19] Eyach virus, isolated from *Ixodes* ticks in France and Germany; S6-1403, isolated in California from a gray squirrel; and mosquito strains from Indonesia are related to but distinct from CTF virus and have not been confirmed to cause human illness.[2,28] RNA hybridization studies of CTF viral strains from a 33-year interval found minor heterogeneity, thus suggesting that a single gene pool has been maintained by mixing of viral strains and by constraints on viral replication within tick vectors and vertebrate hosts. A wide variety of small and large mammals are infected naturally with the virus, but clinical illness develops only in humans. Experimental infection of rhesus monkeys, hamsters, and mice produces hematologic changes similar to those occurring in human infections.[21]

Epidemiology

Cases occur sporadically in association with the habitats of the wood tick *Dermacentor andersoni*. Most cases occur in May and June, when adult ticks are most active, but infections from March to November have been reported. Infections are acquired principally in the western part of the United States and Canada in the known geographic distribution of the vector (Fig. 171-1).[8,11-13] In rare cases, CTF has occurred in persons who had not traveled to areas of known risk, such as those exposed to ticks brought home on the clothing of family members and, in one case, by transfusion.[7,35,41,45] The annual incidence of disease in the Rocky Mountain region, approximately 3/million residents, is declining, possibly a result of a larger elk population that has reduced habitats of small vertebrate hosts.[4]

CTF virus is maintained in a 2- to 3-year cycle among small mammals, principally rodents, and *D. andersoni* ticks (Fig. 171-2).[5,13,19] Once infected in the larval stage, ticks remain infected through the nymphal and adult stages (trans-stadial transmission). Larvae are infected by viremic rodents. After molting, they carry the virus through the winter, and as nymphs, they infect other rodents and renew the cycle of transmission the following spring. Humans become infected incidentally by the bite of infected adult ticks.

The least chipmunk *(Eutamias minimus)*, the golden-mantled ground squirrel *(Spermophilus lateralis)*, and the porcupine *(Erethizon dorsatum)* appear to be the primary hosts for larval, nymphal, and adult *D. andersoni;* secondary hosts include rock mice *(Peromyscus maniculatus)*, meadow voles *(Microtus pennsylvanicus)*, and pine squirrels *(Tamiasciurus hudsonicus)*.[6]

D. andersoni is found exclusively in the high plains and in mountainous terrain between 4000 and 10,000 feet in altitude in the geographic distribution previously mentioned. The specific microhabitats where infected ticks are most prevalent are south-facing slopes with open stands of ponderosa pine, moderate shrubs, and rocky surfaces that provide favorable habitats for the intermediate rodent hosts.[6,34] Both male and female adult ticks can transmit infection to humans, and the period of attachment required for transmission of the virus may be very brief.

Clinical Manifestations

A history of a tick bite or tick exposure is given by more than 90 percent of patients.[22] The incubation period usually is 3 to 4 days, with a range of 0 to 14 days after known exposure to a tick.[4,22] The onset typically is abrupt,

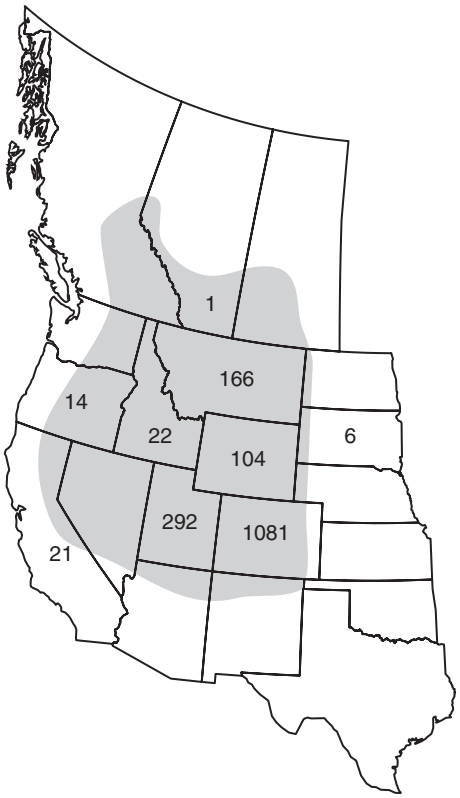

FIGURE 171-1 ■ Geographic distribution of *Dermacentor andersoni* ticks and reported cases of Colorado tick fever, 1980 to 1991.

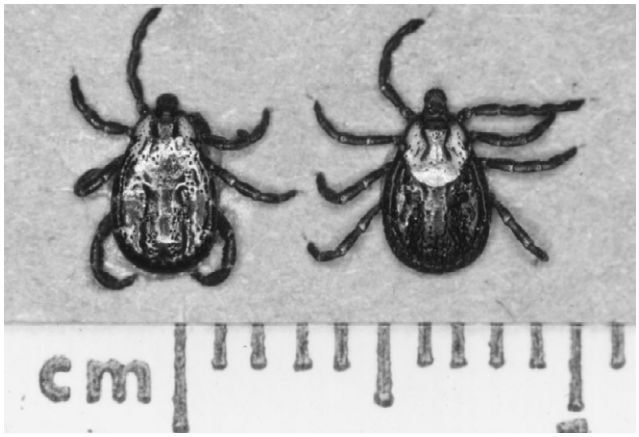

FIGURE 171-2 ■ Adult male *(left)* and female *(right) Dermacentor andersoni* ticks. Both can transmit Colorado tick fever virus.

with fever, chills, malaise, headache, retro-orbital pain, myalgia, lumbar pain, and hyperesthesia. Nausea, vomiting, and abdominal pain occur less frequently. Upper respiratory tract symptoms usually are absent, although conjunctival injection may develop. Lymphadenopathy and hepatosplenomegaly are found in some patients. Maculopapular and petechial eruptions have been observed in 5 to 12 percent of cases.[43]

The disease classically is diphasic; an initial attack lasting 2 to 3 days is followed by an equal interval of defervescence and a second and, rarely, a third recurrence. However, this saddleback pattern is absent in more than 50 percent of cases. Symptoms resolve several days after the second bout of fever, but prolonged asthenia lasting for several weeks is a typical finding, especially in adults.[22]

Leukopenia is a hallmark of the illness. The mean initial leukocyte count is 3900/mm^3, which diminishes to a nadir 5 to 6 days after the onset of illness, often during the period of remission. A left shift with an absolute neutropenia and relative lymphocytosis is a usual finding. Examination of bone marrow aspirates shows maturational arrest in the granulocytic series, with absent mature forms and numerous metamyelocytes and myelocytes. Megakaryocytes are depleted, and a reduced peripheral platelet count (<150,000/m^3) is found in most patients; however, thrombocytopenia rarely reaches a level of clinical significance.[26,33]

Uncomplicated recovery is the rule. Epididymo-orchitis, pneumonitis, hepatitis, and pericarditis have been reported as complications, but the most serious complications are encephalitis and hemorrhage,[15,20,22,24,32] which have been reported nearly exclusively in children younger than 10 years.[11,22,44] Three deaths have been reported, all in children who exhibited signs of generalized bleeding accompanied by a reduced platelet count.[22] Examination of the bone marrow in one child disclosed a generalized depression of myeloid and erythroid elements and a marked reduction in megakaryocytes. Central nervous system signs consistent with meningitis and encephalitis have been reported in both children and adults. Examination of cerebrospinal fluid disclosed elevated protein and mononuclear cell pleocytosis in the few cases that have been described.

D. andersoni is a vector for both CTF and Rocky Mountain spotted fever.[2] Although dual isolation of CTF virus and *Rickettsia rickettsii* from the same tick has not been reported, a concurrent rickettsial infection could not be discounted in all of the previously mentioned fatal cases attributed to CTF. Furthermore, a dual infection could develop in an individual exposed to more than one tick.

CTF virus is teratogenic in experimentally infected mice, but few clinical data are available on the teratogenic potential of the virus in humans.[23] One pregnant woman aborted 2 weeks after having an illness; and in an infant delivered 6 days after the onset of CTF in the mother, a febrile illness with leukopenia developed at 3 days of age, thus indicating a possible vertically acquired infection. In a single reported instance, a second attack of CTF has been documented, which indicates that immunity may not be permanent.[22]

The combined historical elements of tick exposure and outdoor activity in an enzootic area should suggest the diagnosis in patients with a spring-summer grippe-like illness. In a controlled study, abdominal pain, pharyngitis, and rash were less common symptoms in patients with CTF than in patients with other acute illnesses in the same season. Although Rocky Mountain spotted fever occurs rarely in the states in which CTF is prevalent, the possibility of this potentially fatal disease should be considered in the differential diagnosis. Helpful differentiating features include the rarity of a petechial rash in CTF and its biphasic course. Tick-borne relapsing fever also follows a remitting course, but it has a more acute and toxic onset; splenomegaly occurs commonly, and remission is by crisis. The geographic distribution of the diseases overlaps; however, human encounters with the argasid (soft) tick vectors of relapsing fever (*Ornithodoros* ticks) are likely to occur in cabins and other protected areas.

Eyach virus has been implicated in central nervous system infections and polyradiculitis in Europe. However, its tick-borne transmission from *Ixodes ricinus* that also transmits *Borrelia*, *Anaplasma*, and Kemerovo group viruses has prevented establishment of a clear interpretation.

Pathophysiology

Experimental infection of rhesus monkeys, rodents, and human marrow cells in vitro has shown that CTF virus infects the erythropoietic elements (erythroblasts to reticulocytes) at an early stage of infection.* After the infected cells mature and are released into the peripheral circulation, the virus persists intracellularly, where it has been identified by electron microscopy.[16,39] CTF virus has been cultured from circulating erythrocytes for up to 120 days after the onset of illness.[25] Red cell survival evidently is not shortened, and infected cells circulate in the presence of neutralizing antibody. Prolonged viremia has not been associated with either a protracted or a more severe course of illness. Infected CD34$^+$ progenitor cells and impaired mononuclear cell production of colony-stimulating factors may contribute to the acute aregenerative cytopenia.[40] High levels of serum interferon-γ correlate with fever during the acute phase of illness.[1]

Laboratory Diagnosis

Direct immunofluorescent examination of blood smears for intraerythrocytic viral antigen is an accessible and rapid approach to laboratory diagnosis.[14] However, polymerase chain reaction (PCR) analysis and viral culture of blood or serum samples are more sensitive.[27] Of all cases diagnosed by seroconversion, 96 percent are identified by isolation of virus from acute or convalescent blood samples in baby mice or Vero or BHK cells.[10,14] Freezing and thawing of the clot should be avoided. Virus has been isolated from a blood clot that had been refrigerated for

*References 14, 16, 21, 27, 39, 41.

14 months. Serologic diagnosis by demonstration of fourfold rises in neutralizing, complement-fixation, immunofluorescent, or enzyme-linked immunosorbent assay (ELISA) antibody is confirmatory. ELISAs that distinguish between CTF and Eyach virus antibodies are available. Neutralizing antibody rises slowly; only a third of patients had detectable neutralizing antibody 10 days after onset, but fourfold rises appeared within 30 days of onset in 92 percent.

Treatment

No specific therapy is available. Because thrombocytopenia may occur and hemorrhage is a reported complication in children, antipyretics that interfere with coagulation should not be used.

Prevention

Repellents containing permethrin should be sprayed on clothing, and repellents containing diethyltoluamide (DEET) or picaridin should be applied to exposed skin. Long pants should be tucked into socks and shirts tucked into slacks. Clothing, gear, and skin should be inspected frequently for attached ticks. Light-colored clothing facilitates such inspections. One case of human-to-human transmission by transfusion of infected blood has been reported.[7] Persons with documented CTF should be prohibited from donating blood until the often prolonged viremia has cleared.[41]

BANNA VIRUS

Banna virus, the type species of *Seadornavirus*, has been isolated from patients with febrile illness and encephalitis in China and is believed to be a major contributor to previously unexplained cases of viral encephalitis in that country and, possibly, within a broader region of East and Southeast Asia.[3,29,31,43] Although its transmission cycle has not been defined, a mosquito-borne–vertebrate cycle and possibly tickborne-vertebrate cycle have been surmised by its isolation from various mosquito and tick vectors and from pigs and other vertebrates that could act as intermediate hosts. A common ancestry and taxonomic link to rotaviruses have been indicated by similarities in the viruses' gene organization and certain gene segment sequences (e.g., for VP9), as well as their morphology.[36] Two geno/serotypes (A and B) have been defined with broadly overlapping geographic distributions. The virus has been isolated from far-northern China, Mongolia, southern China, Vietnam, and Indonesia and from *Culex tritaeniorhynchus*, *Culex pipiens pallens*, and other mosquito vectors that also transmit Japanese encephalitis virus, and, in one study, the virus was implicated as the cause of 14 percent of cases in a nominal Japanese encephalitis outbreak.[31,38] Clinical symptoms in confirmed cases have included fever, arthralgia, and encephalitis, but few details have been published. The potential public health impact of Banna virus infection could be substantial, but means to confirm a specific diagnosis are not widely available; broader application of real-time PCR assays that have been developed and field studies are needed to define the burden of disease and need for public health intervention. In addition, several related seadornaviruses that have been described in China (e.g., mosquito-borne Liao Ning virus) are suspected to cause human illness but currently remain orphan agents.

KEMEROVO AND RELATED VIRUSES

The Kemerovo serogroup comprises tick-borne Kemerovo, Tribec, and Lipovnik viruses, which may have descended from ancestral mosquitoborne orbiviruses.[9] Kemerovo virus was isolated from the cerebrospinal fluid of two patients with encephalitis and from ticks in the Kemerovo region of Russia; seroconversion was demonstrated in 10 other patients with meningoencephalitis with tick bites and in whom Russian spring-summer encephalitis was excluded.[8,30] The virus is transmitted in an *Ixodes persulcatus*–rodent cycle. Lipovnik virus has been reported in neurologic infections in the former Czechoslovakia, where flaviviral tick-borne encephalitis is endemic; one study showed seroconversion to Lipovnik virus in half of the patients with encephalitis who were studied, including some with suspected dual infection with tick-borne encephalitis virus.[30] This finding seems plausible because both viruses are transmitted by *I. ricinus* ticks, and multiple exposure to singly infected ticks or infection with a dually infected tick may be possible. In addition, serologic evidence of Lipovnik or Tribec infection was reported in patients with chronic polyradiculoneuritis; however, spirochetal infection was not ruled out in these cases. The increasing geographic range of *I. ricinus* ticks in Europe to more northerly latitudes and higher elevations, attributed to global warming, could lead to increased transmission of these orbiviruses, as has been observed with tick-borne encephalitis virus.

On the basis of serologic rises in patients with acute febrile illness diagnosed clinically as Rocky Mountain spotted fever, a Kemerovo-related virus is suspected to occur in the southwestern region of the United States. Patients with a history of a tick bite or tick exposure, whose sera were negative for *R. rickettsii*, demonstrated fourfold or greater changes in immunofluorescent titers to Lipovnik and Six Gun City viruses (Kemerovo group).[45] Rises in immunofluorescent antibody titers to 128 to 512 suggested recent infection with a Kemerovo-related virus, possibly a novel agent or related to rabbit syncytium virus, which is enzootic in the United States. The patients had acute febrile illnesses with myalgia, vomiting, and severe abdominal pain, along with leukopenia, thrombocytopenia, and anemia, similar to Rocky Mountain spotted fever. No agent has been isolated, but neither was the possibility of *Ehrlichia* infection excluded.

ORUNGO VIRUS

Orungo virus is unrelated antigenically to the other orbiviruses. Infection is prevalent in western, central, and eastern Africa and apparently is transmitted in a sylvatic

monkey, with an *Aedes* mosquito cycle similar to that of yellow fever. Human-to-human transmission by *Anopheles* mosquitoes is speculated to occur. The virus has been isolated from patients with fever and headache, and serologic evidence of infection has been reported in outbreaks of illness characterized by fever, headache, myalgia, nausea, and vomiting. Seroconversion has been observed in patients studied during yellow fever outbreaks, presumably because of concurrent transmission of the viruses. The virus also was isolated from the blood of a child with seizures and flaccid paralysis.[17,37]

LEBOMBO VIRUS

Lebombo virus is not grouped antigenically. The virus was isolated first from *Aedes circumluteolus* mosquitoes in South Africa. Subsequently, the virus was recovered from a Nigerian child with nonspecific febrile illness; the virus also was isolated from rodents and mosquitoes in Nigeria.[37]

CHANGUINOLA VIRUS

Changuinola virus belongs to an antigenic complex of 12 principally phlebotomine-borne orbiviruses. The virus is transmitted in Panama among forest mammals and *Phlebotomus* flies. Only one human case has been reported—a nonspecific febrile illness in a mosquito catcher.

CHAPTER 172

Rotavirus

Mary Allen Staat • Monica Malone McNeal • David I. Bernstein

Before the introduction of rotavirus vaccines, rotaviruses were the single most important cause of severe infantile gastroenteritis worldwide.[349,455] In the United States, rotaviruses were estimated to cause 55,000 to 70,000 hospitalizations, 205,000 to 272,000 emergency department visits, and 20 to 60 deaths in young children annually before rotavirus vaccines were approved and universally recommended for use in infants.[80,196,233,285] The total health care system costs associated with rotavirus disease in the United States were estimated to be $319 million, and the total costs to society were $893 million.[516] On a world scale, rotaviruses were estimated to be responsible each year for 2 million hospitalizations and 352,000 to 592,000 deaths in children younger than 5 years.[349-351,455,460] For these reasons, rotaviruses were a high priority for vaccine development, leading to the introduction of two effective vaccines.[74]

Transmission of rotaviruses occurs by the fecal-oral route, providing a highly efficient mechanism for universal exposure that leads to infection of almost all children around the world by the age of 5 years despite socioeconomic and cultural differences. The symptoms associated with rotavirus disease are typically diarrhea and vomiting accompanied by fever, nausea, anorexia, cramping, and malaise that can be mild and of short duration or produce severe dehydration.[227,405,445] Severe disease occurs primarily in young children, most commonly in children younger than 24 months.[362,363,393,447] Treatment of disease is largely supportive and includes nonspecific methods, such as rehydration therapy for replacement of body fluids and electrolytes.[235]

Approximately 90 percent of children in both developed and developing countries experience a rotavirus infection by the time they reach 3 years of age.[393,481] Natural rotavirus infection provides protection especially against subsequent severe illnesses, but reinfection is common and can occur multiple times in young children in poorer socioeconomic settings.[38,85,123,290,481] Further,

infection and illness in adults and the elderly occur commonly and can be acquired within families with an ill infant.*

Because of the frequent occurrence of rotavirus infections and the reduced severity of illness typically associated with sequential infections, rotavirus vaccines were developed to protect against severe disease in early childhood. The first vaccine licensed in 1998[1,329] was effective but was quickly withdrawn because of its association with intussusception.[71,75] Two new vaccines were licensed in the United States for use years later, the first in 2006 and the second in 2008.[2,3,108,348] Since the introduction of these two vaccines, there has been a remarkable decrease in rotavirus disease wherever these vaccines have been used.† However, in resource-poor countries, the decreased efficacy of both vaccines is striking and will need to be further studied.‡

HISTORY

Viruses with morphologic features later associated with rotaviruses were observed first by electron microscopy in 1963 in intestinal tissues and rectal swab specimens from mice and monkeys.[7] These agents, called epizootic diarrhea of infant mice virus and simian agent 11, respectively, were described as 70-nm particles that had a wheel-like appearance. Hence, they were later designated "rota" viruses from the Latin word for wheel. The correlation between these viruses and human diarrheal disease was reported first in 1973 by Bishop and colleagues, who used electron microscopy to examine biopsy specimens of duodenal mucosa from children with acute gastroenteritis.[40] Within a short time, these and other investigators confirmed the association between the presence of rotavirus in feces and acute gastroenteritis.[39,120] In addition to their distinctive morphologic features, these human viruses along with their animal rotavirus counterparts were later shown to share a group antigen[520] and have been classified as members of the *Rotavirus* genus within the Reoviridae family. In 1980, particles that were indistinguishable morphologically from established rotavirus strains but lacked the common group antigen were discovered in pigs.[53,415] This finding subsequently led to the identification of rotaviruses belonging to six additional groups (B to G) on the basis of common group antigens, with the original rotavirus strains classified as group A.[416]

CLASSIFICATION OF ROTAVIRUS

Rotavirus Groups

Rotaviruses have been classified into groups on the basis of antigenic properties of the VP6 protein and more recently the amino acid sequences of this inner capsid protein.[416] There are currently five groups (A to E) and evidence to establish three additional groups (F to H). Only groups A to C have been associated with human diseases, and most known cases of rotavirus gastroenteritis are caused by group A strains. Group A rotaviruses are the strains to which vaccine development has been directed.

Rotavirus Genotypes

The two outer capsid proteins, VP7 and VP4, contain neutralization epitopes.[178,201] Early classifications of rotaviruses were based on cross-neutralization assays with panels of monoclonal antibodies to characterize the VP7 or G type, referring to the glycosylated structure of this protein, or P type, referring to the protease sensitivity of the VP4 protein. Most classification is currently based on sequence analyses or genotypes of the VP4 and VP7 gene,[157,169] and 27 G types and 35 P types have been described to date.[293] The genetic analysis of all 11 gene segments of rotavirus was recently used to classify and to compare rotavirus strains with the scheme detailed in Table 172-1.[293] The nomenclature for rotaviruses includes the G type and P type. The numeric designation for G serotypes and G genotypes is identical. Therefore, only a single number for G types, such as G1, is used. However, P serotypes and P genotypes are not the same. P types are classified into both serotypes (e.g., P1A, P1B, P2A, P3, P4, P5, P8) and their respective genotypes (e.g., P1A and genotype 8, P1B and genotype 4, P2A and genotype 6, P4 and genotype 10, P5 and genotype 3, P8 and genotype 11). Designation of each P genotype is included in square brackets after the term P. The P genotype classification is most commonly used. The G and P combinations may be written as either G1P[8] or P[8]G1.

Rotaviruses, similar to other viruses with segmented genomes, have the ability to form reassortants. When a cell is coinfected with two different rotaviruses, gene segments from each parent virus can be incorporated into new progeny viruses. The gene segments from different viruses can segregate independently, and the new viruses produced can contain genes from both parents. Rotaviruses have an extremely wide host range, but natural cross-species infections, particularly between animals and humans, may be rare. Nevertheless, numerous human isolates appear to be animal strains or animal-human rotavirus reassortants as determined by sequence analyses.[112,118,119,159,294] This property of reassortment has contributed to the diversity of G and P types found throughout the world. As more and more sequences are determined for all 11 genes of rotavirus isolates, more information will be gained on the origin and evolution of human and animal strains.[359]

Most human surveillance studies initially determined the G and P types for rotavirus isolates. In the past, the most common G types were G1 through G4 and G9.[158,161,180,207,420] More recently, other G types have emerged, including G5, G8, G10, and G12 in various regions around the world.* The most common types for

the P protein are P[8] and P[4] in addition to the more recently described P[6]. The global distribution of G and P genotypes can vary greatly by location and time or, as was found in some studies, may vary little over sequential seasons.[382] A review by Santos and Hoshino has summarized rotavirus genotypes from 124 studies performed between 1989 and 2004 and included data on 45,571 strains collected from 52 countries on five continents.[420] The four common G types, G1, G2, G3, and G4, with either P[8] or P[4], represented more than 88 percent of the strains identified worldwide during this period. Genotype G9, containing either P[8] or P[6], was found to be an emerging strain in a number of different locations.[161,420] A study of circulating strains in the United States during 1996-2005 found that G1P[8] was the most prevalent strain during this period.[160] Lower frequencies of the other common strains (G2P[4], G3P[8], and G4P[8]) varied during different years with some unusual combinations of G and P types (e.g., G12P[6] , G6P[9], and G3P[9]). G9 strains, which emerged in 1995, were detected for several seasons but then were not detected for four subsequent seasons. However, in some sites during those same years, a high prevalence of G2 and G9 strains was detected.[158]

The impact of rotavirus vaccines on circulating rotavirus strains is beginning to be studied. International and national surveillance programs around the world isolate and characterize circulating strains. Recent reports have shown that the strains isolated are still the most common (G1-4, G9 with P[8], P[4], and P[6]) but with a growing number of G8 and G12 isolates.* A recent report on strain surveillance in the United States found that G1strains were the dominant G type from 2005 to 2007 but that G3 was the most frequently detected strain in the 2007-2008 season.[207] Unusual combinations or reassortants with animal strains and even vaccine strains have been described.[62,352,432,454] Of interest are the strain surveillance studies in Australia during the period of vaccine introduction. G1P[8] was the most common strain from 2007 to 2010, followed by G2P[4], with G9P[8], G3P[8], and G4P[8] detected at lower frequencies. Overall, there seemed to be an increase in G2P[4] strains in areas using Rotarix vaccine and an increase in G3P[8] in areas using RotaTeq. In the 2011 season, G2P[4] became the dominant strain (51%), with G1P[8] still representing 26 percent of the detected isolates in Australia.[237,238] It is still unclear if vaccines are exerting selection pressure on circulating strains or if the recent findings represent the normal variation of strain diversity that was seen even before vaccine introduction.

Non–Group A Rotavirus Strains

Whereas most rotavirus disease in humans is caused by group A rotaviruses (the focus of this chapter), disease in humans may also occur from infection with group B and C strains of rotavirus. Epidemics of group B rotavirus have been reported in China, particularly in adults.[81,145,208,322,368] Seroprevalence studies have identified group B rotavirus infections in other areas, such as Hong Kong, Myanmar, Thailand, Australia, Bangladesh, Canada, England, Sweden, Africa, and the United States, although the prevalence is lower than in the epidemic regions of China.[416] Group C infections have been reported largely from Japan,[81,256,377,477] but they also have been detected in other parts of Asia, Australia, Europe, Central and South America, and Africa* and in the United States.[216] Serologic evidence has shown group C infection rates of 30 to 43 percent in England[214] and the United States.[403] Unlike group A rotavirus, group B and C rotaviruses appear to cause disease predominantly in children older than 3 years and in adults.[145,256,330] If infection is suspected, the diagnosis is suggested by electron microscopic detection of the typical rotavirus particles with a negative test result by the routine rotavirus assays that detect only group A rotaviruses. The detection of typical RNA migration patterns by polyacrylamide gel electrophoresis of RNA is also suggestive. Polymerase chain reaction (PCR) analysis and enzyme-linked immunosorbent assay (ELISA) have been described.[168,213,330,473] Outbreaks caused by waterborne or food-borne spread of group B rotavirus in China[209] and group C rotavirus in Japan[254,257,377] have been reported, although person-to-person spread also has been implicated.[145] Outbreaks usually involve older children and adults, but infants can be infected as well.[216] Group C rotaviruses have been associated with extrahepatic biliary atresia.[403,428] In one study, group C rotavirus RNA was detected in liver specimens from 10 of 20 patients with biliary atresia; however, there were no controls for comparison.[403] As the prevalence of group A rotavirus infections declines with the implementation of rotavirus vaccine programs, it will be important to monitor the burden of group B and C rotaviruses in the future.

PROPERTIES OF ROTAVIRUSES

Early visualization of the rotavirus particle by cryoelectron microscopy revealed a double-shelled structure with icosahedral symmetry and a T = 13 icosahedral lattice for the two outer layers. The outer shell is composed of two structural proteins, VP4 and VP7, which form capsomers that radiate from the inner capsid composed of the major structural protein, VP6.[386] This inner shell surrounds a core containing the segmented, double-stranded RNA viral genome and three additional structural proteins, VP1, VP2, and VP3 (Fig. 172-1).

Detailed analysis of the outer layer by subnanometer-resolution cryoelectron microscopy suggests that it is composed of 780 molecules or 260 trimers of the VP7 glycoprotein and is ~35 Å thick. Sixty trimers of the VP4 protein, 120 Å in length, are anchored to the VP6 layer. The VP6 layer is also composed of trimers, with one trimer of VP7 sitting on top of a VP6 trimer. The VP4 protein forms spikelike projections as they extend through and beyond the VP7 layer.[136,528] Thus, the full diameter of the mature rotavirus particle, including the VP4 spikes, is approximately 1000 Å. There are 132 aqueous channels in the outer layer that are positioned over 132

channels within the perforated VP6 intermediate shell. These channels are ~140 Å deep and are classified into three types on the basis of their location relative to the icosahedral symmetry axes. Besides interactions between the two layers of VP7 and VP6, both proteins interact with VP4 in these aqueous channels.[265] Further examination of the rotavirus structure by cryoelectron microscopy has indicated that the inner layer composed of 120 subunits of VP2 molecules not only encloses the viral genome but interacts with it as well.[385] This interaction has been found to cause significant conformational changes in the VP2 structure. Within the VP2 layer there are also 11 or 12 copies of VP1, the viral polymerase, and VP3, the viral capping enzyme.[296]

The genome of rotavirus is composed of 11 segments of double-stranded RNA that encode the six structural proteins—VP1 to VP4, VP6, and VP7—and six nonstructural proteins designated NSP1 to NSP6 (Table 172-1). Each segment encodes one known rotavirus protein except segment 11, which encodes both NSP5 and NSP6 using alternative open reading frames. The genome segments range in size from approximately 660 to 3300 base pairs, and their encoded proteins have molecular weights of approximately 12,000 to 125,000. The functions of the structural and nonstructural viral proteins have been at least partially determined and are briefly listed in Table 172-1. The structure and function of the nonstructural proteins are detailed in a review by Hu and colleagues.[205]

The double-stranded RNA genome segments of rotavirus can be extracted from viral particles and separated by polyacrylamide gel electrophoresis into 11 distinct bands visualized by silver staining (Fig. 172-2). Each rotavirus strain has a characteristic RNA profile or electropherotype, a property that has been used extensively in epidemiologic studies of these viruses. The characteristic RNA electrophoretic pattern of group A rotaviruses consists of four size classes containing segments 1 to 4, 5 and 6, 7 to 9, and 10 and 11. RNA segments of strains belonging to less well characterized rotavirus groups (i.e., groups B to G) also can be separated into four size classes, but the distribution of segments within these classes differs from group to group.[415,416]

Entry and Replication

The major recognition protein for host cell receptors is the outer capsid VP4 protein of rotavirus. Rotaviruses are activated by cleavage of the VP4 protein by trypsin-like

TABLE 172-1 **Rotavirus Gene Segments and Properties of the Encoded Proteins**

RNA Segment	Encoded Protein	Properties of Protein
1	VP1	Structural inner core protein RNA transcriptase and RNA binding
2	VP2	Structural inner core protein RNA binding
3	VP3	Structural inner core protein Complexes with VP1; RNA binding; guanylyltransferase and methyltransferase activity
4	VP4	Outer capsid protein Receptor binding; hemagglutinin and neutralization protein
5	NSP1	Nonstructural protein RNA binding; possible suppression of host innate antiviral response
6	VP6	Intermediate capsid protein Group and subgroup antigen; necessary for transcription
7	NSP3	Nonstructural protein RNA binding and control of viral translation; inhibits host translation
8	NSP2	Nonstructural protein Multifunctional enzyme activity; interacts with NSP5 in formation of viroplasm
9	VP7	Outer capsid protein Neutralization protein
10	NSP4	Nonstructural protein Multifunctional protein; essential for replication, transcription, and morphogenesis; enterotoxin
11	NSP5	Nonstructural protein Binding to NSP2 to form viroplasm
	NSP6	Nonstructural protein Not encoded by all rotavirus strains; RNA binding; role not clearly determined

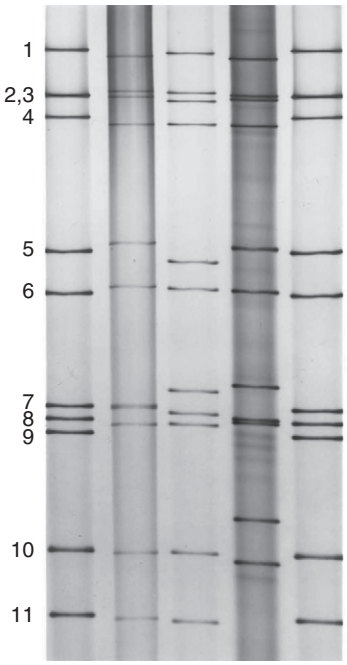

FIGURE 172-2 ■ Polyacrylamide gel electrophoretic patterns of genomic RNAs obtained from group A human rotaviruses and visualized by silver staining. The patterns demonstrate the characteristic four size classes of RNA separated into groups of 4, 2, 3, and 2 segments each. Human rotavirus strains included (from left to right) lane 1, Wa; lane 2, 248 strain; lane 3, 456 strain; lane 4, DS-1; lane 5, Wa.

proteases into VP5* and VP8* proteins, which remain virus associated.[15,24,172,236] Determining cell receptors for rotavirus has been an area of extensive study. Early studies determined that some animal but not human rotavirus strains use sialic acid on the cell surface and that attachment is mediated by VP8*.[305] Additional studies have indicated that multiple molecules are probably involved in virus attachment and entry, including heat shock cognate protein 70 (hsc70), ganglioside compounds, and integrins including $\alpha_2\beta_1$. VP7 has been shown also to interact with cellular integrins.* Another study, using a human rotavirus strain with a specific VP4 type (P[14]), has shown binding of the VP8* protein to a glycan characteristic of A-type histo-blood group antigens (HBGAs).[204] Two additional reports have shown that rotaviruses with different VP4 proteins, including the VP4 type of the study cited, can also bind to different HBGAs including types O, A, and AB. In addition, binding to human saliva, milk, and synthetic HBGA oligosaccharides was demonstrated.[206,272] HBGAs have been shown to be important receptors for noroviruses and are genetically controlled, which may have importance in determining susceptibility to rotavirus in the human population.

Studies to determine how rotavirus enters a cell after attachment have suggested endocytosis or a process similar to enveloped virus fusion as the mechanism for viral internalization, but again the process is not fully elucidated.[273,431,518] From a number of studies, it has been shown that the outer capsid proteins VP5* and VP8* undergo conformational changes that may also involve the VP7 protein during attachment and entry into the cell.[215,431,518,529]

For replication to begin, the outer capsid proteins must be removed to yield a VP2-VP6 double-layered particle. This particle becomes transcriptionally active when the viral RNA-dependent RNA polymerase (VP1) and the RNA capping enzyme (VP3), attached to the VP2 shell, start to synthesize the 11 viral mRNAs.[215,360] The capped non–poly A plus-strand RNAs are extruded from the virus cores through channels in the VP2 and VP6 protein layers at the 12 vertices of the viral particles and subsequently are translated into viral proteins in the cell cytosol. A number of studies using short interfering RNAs (siRNAs) have helped elucidate the various steps of viral replication and how the different viral proteins are involved.[435] Two nonstructural proteins, NSP2 and NSP5, have been found to be involved in the formation of large inclusions or viroplasms.[67] It is in the viroplasms that the assembly of virion precursors is initiated. Particle assembly may be initiated by the formation of complexes within the viroplasm that contain plus-strand RNAs from the 11 genome segments along with VP1 and VP3. Although the mechanism is not fully known, the virus assembles and packages one of each of the plus-strand RNAs within individual precursor viral complexes. On interactions with VP2, a single round of minus-strand RNA is synthesized and the 11 double-stranded RNA genome segments are produced.[297,298] VP6 trimers interact with the VP2 core, and a double-layer particle is completed.[189,297,298,341] The double-layer particles then bud into the rough endoplasmic reticulum after their association with the NSP4 transmembrane glycoprotein.[436] VP4 is added either before entry into the endoplasmic reticulum or sometime thereafter. The other rotavirus glycoprotein VP7, which becomes sequestered within the rough endoplasmic reticulum, is added to complete the formation of a mature viral particle.[469,470] These mature viruses accumulate within the lumen of the rough endoplasmic reticulum until cell lysis occurs.

Immunity

Much has been learned about the immune response to rotavirus, but the key question of what provides protection from infection or disease remains unanswered. Rotavirus infections clearly induce a humoral immune response beginning with production of IgM antibodies and later including IgA and IgG antibody.[121,182,299,402] Infection also induces local, intestinal antibodies that are predominantly IgA but also initially include IgG and IgM.* Cell-mediated immunity, including lymphoproliferative responses, also can be transiently detected after infection in adults.[211,283,339,340,408]

An obvious place to begin to understand rotavirus immunity is to determine the effectiveness of previous rotavirus infections in prevention of subsequent infections and disease. The important questions relate not

*References 21, 148, 187, 188, 273, 536.

*References 29, 111, 121, 182, 211, 283, 299, 339, 340, 402, 408.

only to the degree of protection but also to whether protection is serotype specific. As discussed before, there are multiple serotypes of human rotavirus based on neutralization epitopes on the VP4 and VP7 outer capsid proteins. Thus, protection may be limited to those strains that share neutralization epitopes, or it may be associated with the development of other B- or T-cell immune responses to shared epitopes.

Many investigators have reported that natural rotavirus infections produce incomplete protection, but little doubt exists that previous infections protect against severe disease associated with reinfection. In a large study, protection from both rotavirus reinfection and rotavirus diarrhea increased with each new infection,[481] but sequential infections even with the same serotype have been reported. In the initial study reporting rotavirus disease with reinfection by the same serotype, the investigators noted that protection of young children in a Japanese orphanage lasted 6 months then declined after 1 year.[84] This study noted a close correlation between titers of serotype-specific antibody and protection. Some animal studies also support a role for serotype-specific protection. Thus, in a study with piglets, immunization with reassortant viruses containing either the VP4 or the VP7 protein of the same serotype was protective, whereas immunization with reassortants containing heterotypic genes for these proteins was not protective.[200] In other studies using mice, this association was not as clear,[511] and protection was better correlated to serum and intestinal levels of IgA.[300,303]

Although reinfections with rotavirus appear to be common, some studies have shown protection that lasts at least 1 year.[31,38,502] In one of the first studies of protection, neonates infected within the first 2 weeks of life were protected against severe disease but not against reinfection.[38] In another study, infants who developed a symptomatic or an asymptomatic rotavirus infection during the first year of study were protected against contracting a subsequent rotavirus illness or even an asymptomatic reinfection during the following year.[31] Similarly, when the placebo recipients of a large vaccine trial were observed, a natural rotavirus infection in the first year was found to be 93 percent protective against a symptomatic reinfection in the second year.[502] This protection occurred even though G1 strains that circulated during the first year were responsible for only 66 percent of rotavirus disease in the second year. Other studies conducted in less developed countries and in daycare centers have not shown the same degree of protection.[99,165,481] Differences in these studies may be due to the variation in circulating strains, the magnitude of exposure, the overall health of the infants, or the duration of protection.

Protection has been correlated to both serum and stool antibody titers produced after natural rotavirus infection.[99,110,335,504] In one study, serum antibody levels, especially IgA, were found to be a marker for protection.[482] Reports of a correlation with serotype-specific neutralizing antibody and protection[335] have not been supported in other larger studies.[505] In the largest study, which was conducted in Bangladesh during a 2-year period when four major G genotypes circulated, the titers of both homologous and heterologous neutralizing antibody were significantly lower in patients with acute rotavirus disease than in matched control subjects. However, further analysis could not find a correlation with serotype-specific neutralizing antibody. Thus, protection seemed to correlate better with the magnitude of the response than with specific neutralizing responses.[99,505]

Some results from rotavirus vaccine trials also fail to support a role for serum neutralizing antibody and protection. Thus, immunization with heterologous animal rotavirus vaccines has provided protection in some studies without inducing serum neutralizing antibody to human serotypes.[90,485] In other studies that failed to demonstrate overall efficacy, protection was seen in those who developed the highest antibody titers to the heterologous vaccine,[32,509] again implicating the magnitude of the response rather than specific neutralizing antibody titers. It is possible, however, that serum antibodies are merely markers for the true protective responses in the intestine. Although it is not clear what provides protection, vaccine evaluations of the G1P[8] monovalent vaccine show that heterotypic protection is robust.[128,523]

Animal models also have proved useful for examination of protective immune responses. Initially, large animals, such as piglets and calves, were used, whereas mouse models were limited to the study of passive protection because mice are susceptible to rotavirus diarrhea only for the first 15 days of life. However, the development of an adult infection model in which protection against fecal shedding of rotavirus antigen rather than protection against diarrhea was used as the indicator of active immunity provided much information.[511] Active immunization against both homotypic and heterotypic challenge has been demonstrated in mice, calves, pigs, and rabbits.* Protection has been seen after both oral and parenteral immunization, although what provides protection is not clear. In studies of mice, although no correlation could be found between protection and either serum or intestinal neutralizing antibody, levels of serum or fecal rotavirus IgA did correlate with protection.[300]

The use of these models has been extended to gene knockout mice to distinguish the role of $CD8^+$ cells and antibody in protection. These studies indicated that $CD8^+$ cytolytic cells are important for resolution of an infection, but only antibody could provide protection from a subsequent challenge.[151-153] Other reports have indicated that antibody may be important for complete resolution of a rotavirus infection as well as for protection against subsequent infection.[301,478] A study in mice revealed that oral immunization of mice with a rotavirus that was fully heterotypic to the challenge strain provided nearly complete protection against fecal rotavirus shedding, but this protection was dependent on the ability of IgA antibody to be transported through intestinal epithelial cells.[479] Another report has shown that in IgA-deficient mice, resolution of rotavirus infection is delayed and mice are not protected from subsequent infection with the same virus.[46] These results support the suggestion that protection after live virus immunization may be due to rotavirus-specific IgA, either in the intracellular intestinal cells or in the intestinal lumen, at least in mice.[429,479]

*References 56, 102, 103, 200, 302, 511, 520.

Taken together, these results indicate that the levels, location, and targets of protective antibody as well as the proteins against which it is directed are of immediate importance, provided the results found in mice are relevant to larger animals and humans.

Information on protective immune responses continues to become available and should prove useful in further development of rotavirus vaccines. The absence, to date, of a reliable immunologic marker of protection, however, continues to render efficacy vaccine trials necessary.

Age-Dependent Susceptibility to Rotavirus Disease

In addition to restrictions in interspecies transmission of rotaviruses, age restrictions are associated with rotavirus disease. In animals, rotavirus illness appears to be limited to the first days or weeks of life. Mice are susceptible to rotavirus disease only for their first 15 days of life but can experience a rotavirus infection for their entire lifetime. Similarly, piglets and calves are most susceptible to rotavirus diarrhea during their first days of life.[54,303] In contrast, severe human rotavirus disease occurs most commonly in infants younger than 24 months, but milder rotavirus illnesses can occur throughout our lifetimes.[363,407,447,505,506]

The onset of rotavirus disease in infants has been reported to coincide with the decline of maternal IgG antibody titers.[537] Furthermore, excellent correlations have been observed between responsiveness to the live rotavirus vaccine Rotarix and transplacental neutralizing antibody titers to the vaccine strains (unpublished results). Therefore, early protection from rotavirus disease including asymptomatic neonatal rotavirus infections[38,371] may be due, at least partially, to protection from transplacental antibody that may persist for the first months of life.[32] Mechanisms by which transplacental maternal antibody might protect against intestinal infection are unclear. Passive transfer of neutralizing antibody to the intestine of both humans and animals is associated with protection,* but circulating antirotavirus IgG appears to confer little if any protection in animals.[337,441,442] Possibly, maternal IgG in humans is taken into the intestine, where it neutralizes rotaviruses before infection. Regardless of why rotavirus infection of neonates typically is asymptomatic, these infections have been found to reduce the severity of rotavirus illnesses in older infants.[34,38] For these reasons, two rotavirus strains obtained from neonates have been developed as vaccine candidates,[23,307] and two others obtained more recently from India have been evaluated in a safety and immunogenicity study.[35,118,119]

The reduced severity of rotavirus disease in older children and adults is probably due primarily to immune responses stimulated by previous rotavirus infections. In developed as well as in developing countries, almost all humans experience at least one rotavirus infection by the time they reach 3 years of age, and circulating rotavirus antibody remains detectable indefinitely.[227] Protection against rotavirus infection and disease in children and adults has been correlated with titers of both circulating and intestinal rotavirus antibody.* Although these antibodies have not been established as the effectors of protection, their presence indicates a natural infection that has elicited a protective immune response.

Protection from Breast Milk

Cohort studies have found that the highest incidence of rotavirus-associated diarrhea is in children aged 4 to 6 months, which coincides with the age when weaning from breast-feeding began.[343,393] In addition, several studies have shown that breast-feeding protects against symptomatic rotavirus infections.[98,320,326] In one study, exclusive breast-feeding was found to be protective against severe rotavirus diarrhea, but there was no overall protection during the first 2 years of life, suggesting that breast-feeding simply postpones rotavirus disease to an older age.[98] In another study, breast-feeding was protective against hospitalization for acute gastroenteritis due to rotavirus in infants younger than 6 months.[130] Although breast-feeding alone could be the protective factor, other factors, such as presence of maternal antibody and lack of opportunity for exposure, could also account for this period of protection. Supporting a role of human milk—and factors other than breast milk antibody—in protection against rotavirus is a study demonstrating that infants who received human milk with higher concentrations of the glycoprotein lactadherin were more likely to have asymptomatic rotavirus infections compared with those receiving milk with lower concentrations.[326]

On the other hand, breast-feeding could play a role in limiting the protection induced by rotavirus vaccination.[19,77,314] It is clear that the immune response and protection provided by live oral rotavirus vaccines are less in underdeveloped than in developed countries.[218,219] It has been speculated that this could in part be due to breast milk antibody and other constituents limiting the replication of the vaccine strains as the levels of antibody are higher in women in developing countries.

LABORATORY DIAGNOSIS

Rotavirus infection cannot be reliably diagnosed on the basis of clinical presentation, even in combination with stool examination and nonspecific laboratory tests. Therefore, specific tests have been developed. In the initial epidemiologic studies, electron microscopy was used for identification because of the large number of particles present in stools (>10^{10}) and the characteristic appearance of rotavirus. This technique largely has been replaced by enzyme immunoassay–based and latex agglutination tests, for which kits are available commercially. With the advent of molecular methods, reverse transcription PCR (RT-PCR) to detect conserved genes or real-time RT-PCR has been developed to detect rotavirus and to quantify viral load.[174,226] The use of RT-PCR for the diagnosis of rotavirus disease is discouraged. Because

*References 54, 122, 138, 195, 417, 427, 440, 442.

*References 41, 84, 99, 110, 175, 230, 292, 335, 481, 482, 503, 504.

children may shed rotavirus for prolonged periods and asymptomatic infection commonly occurs, the high sensitivity of RT-PCR will be positive in children without disease in as many as 20 percent of children.[452]

Rotavirus infection, both symptomatic and asymptomatic, also can be identified by changes in rotavirus antibody. ELISAs are used most commonly to measure serum rotavirus-specific IgM, IgA, and IgG levels as well as stool and intestinal antibodies. Specific neutralizing titers also can be measured for each serotype of rotavirus by plaque reduction or focus reduction assays. One ELISA-based antigen reduction neutralization assay has been found to be better suited for the analyses of large numbers of specimens.[240] Serologic detection of infection is more difficult in the first months of life because of the presence of maternal antibodies. Detection of rotavirus IgA, which does not cross the placenta, has been used as a marker for previous infection in the first months of life and also to evaluate immune responses to vaccines.

PATHOLOGY AND PATHOGENESIS

Histologic and Structural Changes in Intestinal Villi

After fecal-oral transmission of rotavirus, infection is initiated in the upper intestine and typically leads to a series of histologic and physiologic changes. These changes have been examined extensively, particularly through experimental infections of animals. Studies in calves revealed that rotavirus infection caused the villus epithelium to change from columnar to cuboidal, which resulted in shortening and stunting of the villi.[304,367] The cells at the villus tips became denuded, whereas in the underlying lamina propria, the numbers of reticulum-like cells increased and mononuclear cell infiltration was observed. The infection started at the proximal end of the small intestine and advanced distally. The most pronounced changes usually but not always[467] were associated with the proximal small intestine. When bovine rotaviruses of different virulence were compared, a low-virulence strain infected the proximal small intestine poorly but infected more villus enterocytes in the mid and distal intestine than did the high-virulence strain.[55,193] Although the low-virulence strain replicated in these cells and caused cytopathic effects, it did not damage intestinal structure or affect function. Similar observations were made after piglets were infected with rotavirus.[100,176,366,462]

The pathologic process of murine rotavirus infection also has been examined in several studies, and the results are similar to those found in larger animals.[6,252,271] Many of these studies have been conducted with heterologous rotavirus strains that require infection with much greater quantities of virus because of the restricted replication of these viruses in mice.[26,50,179,338] The histologic changes induced by these heterologous strains are similar to those found after murine rotavirus infection, even though viral replication is limited after oral inoculation with these viruses. Mice infected during their first 2 weeks of life develop diarrhea.[50] The infection produces time-dependent histologic changes in the intestine, shortening of intestinal villi, induction of apoptosis, and alterations in cell migration kinetics.[50]

A few studies have examined the pathologic changes in the intestines of humans, and the results appeared to be similar to those found in animals.[66,453] Tissue tropism for rotavirus infection in humans appeared to be restricted normally to villi of the small intestine, but it is now clear that infection routinely produces both antigenemia (presence of rotavirus protein in the blood) and viremia (presence of live rotavirus in the blood) in healthy and immunocompromised children[43-45,83,147,164,389] as well as spread to other organs and induction of disease, including meningoencephalitis,[134] elevated liver enzymes,[250] and other systemic diseases as discussed later. It is not clear what virus factors account for increased virulence or induction of extraintestinal disease. Offit and coworkers[336] reported that the virulence of reassortants generated between heterologous rotaviruses tested in a mouse model correlated with the presence of the VP4 protein from the more virulent virus, but a later study with murine-simian rotavirus reassortants revealed no association between the VP4 protein and virulence.[58] In that study, the strongest association between virulence and a gene product was with NSP1, a nonstructural protein. In a study using porcine rotavirus, virulence was associated with VP4, VP7, VP3, and VP5.[199]

Associations between virulence[57] and specific gene segments also were examined in piglets, in which VP4 appeared to correlate best with virulence. In another study with reassortants between a virulent porcine virus and a human strain attenuated for piglets, investigators found that the porcine rotavirus genes encoding VP3, VP4, VP7, and NSP4 were required for virulence in piglets.[199] Whether either of these observations has general applicability or pertains only to a limited combination of rotavirus strains because of specific interactions between their proteins remains to be determined. Until very recently, it was not possible to make specific nucleotide changes within rotavirus genes and to reincorporate the modified gene into new infectious rotavirus particles. However, a system of reverse genetics for rotavirus has now been reported.[242,243,472] Expansion of this system of reverse genetics should permit identification of specific amino acid and protein structural changes that are responsible for rotavirus virulence and attenuation.

Mechanisms of Diarrhea

Although rotaviruses cause severe diarrhea in numerous species, including humans, the mechanisms responsible are not completely understood and include multiple factors. There is evidence that malabsorption due to destruction of enterocytes, villous ischemia, toxin (NSP4), and activation of the enteric nervous system all contribute to diarrhea.[177,390] Infection of mature enterocytes of the small intestines leads to damage and functional abnormalities. However, in animal models, the degree of disease (histologic changes including villous blunting and crypt hyperplasia) is limited and often does not correlate with the severity of diarrhea. Further, diarrhea is often seen before evidence of intestinal disease. Thus, although damage to the mature enterocytes leading to loss of the

enzymatic activities of the brush border decreases absorption of electrolytes, glucose, and amino acids and contributes to rotavirus diarrhea, other mechanisms are also involved.

Secretory mechanisms that contribute to early diarrhea have recently been described. The identification of a viral enterotoxin, NSP4, has increased our understanding of the pathogenesis of diarrhea, as has evidence implicating stimulation of the enteric nervous system.[278,463] NSP4 binding to surface receptors initiates signal transduction pathways, leading to mobilization of intracellular calcium and chloride secretion. NSP4 increases the levels of intracellular calcium[465] by activating a calcium-dependent signal transduction pathway that mobilizes transport of this ion from the endoplasmic reticulum.[135,464] Other reports suggest that NSP4 possesses membrane destabilization activity[59,463] that may result from increased intracellular calcium concentrations, resulting in cytoskeleton disorganization and cell death.[60,61,373,374] Thus, NSP4 binding to intestinal epithelium after its release from infected cells may contribute to altered ion transport and diarrhea. Another possible target for secreted NSP4 is the enteric nervous system, which lies under the villus epithelium. It has been reported that rotavirus infection can activate this system in mice, and drugs that block nerve activity attenuate rotavirus-induced fluid secretion in vitro and attenuate diarrhea in vivo.[278] NSP4 also disrupts tight junctions, allowing paracellular flow of water and electrolytes. Antibody against NSP4 can attenuate rotavirus disease in mice, providing additional evidence for its role in the pathogenesis of disease. More recently, an association between NSP4, secretion of serotonin by enterochromaffin cells, and vomiting was reported.

EPIDEMIOLOGY

Disease Burden

Before the introduction of rotavirus vaccines, rotaviruses were the leading cause of severe acute gastroenteritis in young children worldwide. In children younger than 5 years, an estimated 527,000 children died of rotavirus gastroenteritis each year. The majority of these deaths occurred in children from resource-poor countries in Africa and Asia.[350] Rotaviruses were responsible for approximately 5 percent of all deaths in children younger than 5 years. In addition, in this same age group, there were an estimated 2.4 million hospitalizations, 24 million clinic visits, and 114 million episodes of illnesses attributed to rotavirus each year.[166] The World Health Organization Rotavirus Surveillance Networks estimated that worldwide, 36 percent of diarrhea hospitalizations in children younger than 5 years were due to rotavirus infection.[515]

In the United States, before rotavirus vaccine introduction, rotavirus was estimated to infect nearly every child in the United States by the age of 5 years. Among children younger than 5 years, rotavirus gastroenteritis accounted for 55,000 to 70,000 hospitalizations, 205,000 to 272,000 emergency department visits, and 410,000 physician visits each year.[80,196,233,285] In the pre-vaccine era in the United States, the majority of hospitalizations occurred in young children, with the highest rates in children younger than 3 months (51.8/10,000), slightly lower rates in the 3- to 23-month age group (30.0-34.6/10,000), and the lowest rates in the older age groups of 24 to 35 months (20.5/10,000) and 36 to 59 months (4.1/10,000).[447] Symptomatic disease is less commonly seen in older children and adults because natural infection confers protection against subsequent infection and disease. However, rotavirus still may cause gastroenteritis in these age groups, especially in households with young children or in adults who care for young children with rotavirus.[139,321]

Initial and subsequent rotavirus infections are often asymptomatic. In cohort studies in which infants were observed from birth, as many as 50 percent of initial rotavirus infections were asymptomatic.[190,393,407,481,537] Reports of asymptomatic neonatal infections are common.[34,38,181,192,370] After an initial rotavirus infection, 38 percent of children are protected against a subsequent rotavirus infection, 77 percent are protected against subsequent rotavirus gastroenteritis, and 87 percent are protected against severe gastroenteritis due to rotavirus.[481] Second and third infections due to rotavirus provide greater protection against rotavirus gastroenteritis.

Transmission

Rotaviruses are spread through fecal-oral contamination, generally by close person-to-person contact. Rotaviruses can also be transmitted through contaminated fomites, especially in child care settings and hospitals.[14,65,380,381] Factors facilitating the transmission of rotaviruses include that few infectious virions are needed to cause disease in susceptible hosts (10^3), rotaviruses are shed in high concentrations in the stool (10^{11} particles/gram of human feces),[507] and rotaviruses retain their infectivity for long periods.[143,232,312] Whereas transmission through airborne droplets has been hypothesized, this has not been proved.[387,424] Waterborne transmission has been described,[145,198,209,248] but is unlikely to be a common mode of transmission.

Rotavirus Seasonality and Source of Epidemic Strains

Before the introduction of rotavirus vaccines, in temperate climates there were distinct winter and spring seasonal peaks of rotavirus disease.* In the United States, rotavirus activity typically began in the early winter in the southwest and moved across the country, ending in the northeastern states in the spring.[466] In tropical climates, rotavirus circulates year-round but frequently has peaks during the cool or dry months.† One study, however, suggested that the relative lack of seasonality seen in tropical countries may be due to the high birth rates and transmission rates found in developing countries rather than to environmental conditions.[383] The cause for the

*References 51, 291, 413, 466, 474, 494.
†References 52, 105, 114, 191, 223, 319.

seasonality of rotavirus disease is a topic of considerable interest but remains unknown.

Whereas the transmission of rotavirus infections is thought to be fecal-oral, with little evidence of airborne transmission, a unique pattern of rotavirus infections that follows the general direction of the prevailing winds was observed annually in North America.[260] Rotavirus activity would begin in Mexico and the southwestern United States in mid to late fall and then travel systematically across the continent, ending in the northeastern United States and Maritime Provinces of Canada in the spring. A similar pattern of rotavirus spread was reported for western Europe, where the seasonal peak started in Spain in January and ended in the more northern countries in March.[247] These annual events have no satisfactory explanations. The phenomenon appears to be independent of latitude, which argues against temperature-dependent associations and humidity. Furthermore, the electropherotypes and serotypes of isolates found in different geographic locations can vary, a counterindication for a gradual, physical transmission of rotavirus infections as a wave to the north and east. The introduction of rotavirus vaccines appears to have disrupted this pattern of spread.[343]

Because rotavirus illnesses occurred with seasonal regularity and decreased to almost undetectable levels during the off-season, the virus must be retained in a less active state during most of each year. Retention of human rotavirus in animal reservoirs between seasons is unlikely because of the low interspecies transmissibility associated with this virus, as already discussed. Therefore, the virus may continue to replicate at low levels in humans until conditions are favorable for the annual epidemic. It is also possible that the virus survives in the environment, which provides continuous exposure throughout the year but results in sustained rotavirus illnesses only during seasonal epidemics. Because rotaviruses are shed in extremely high concentrations and can retain their infectivity for long periods, the environment could be a reservoir for human rotavirus and a possible source for the initiation of seasonal epidemics.

To provide clues about the origin of rotavirus strains responsible for epidemics, many extensive studies have been performed to characterize the circulating viruses, primarily by use of electropherotypes and serotypes. From these studies, investigators have determined that rotavirus strains in a specific locale can vary little over sequential seasons or change dramatically, even within a single season.* Furthermore, multiple strains often are present within a region at any period during an epidemic. Because gene reassortment can be extensive after coinfection with rotavirus,† identification of the source of new strains within a defined geographic area is difficult. They could be derived from outside sources, they could be obtained from local reservoirs, or they could arise by gene reassortment of circulating strains.

Since the introduction of rotavirus vaccines in the United States, the traditional pattern of rotavirus seasons in the United States has become more variable, failing to demonstrate the typical southeast to northeast spread of rotavirus activity.[115] In the 2007-2008 and 2008-2009 seasons, the onset of the season was delayed and duration was shortened compared with the 2000-2006 pre-vaccine season.[70] In addition, during the 2009-2010 season, the threshold for the start of the rotavirus season was not observed for the first time in the United States.[457,458]

CLINICAL DISEASE

The incubation period for rotavirus is approximately 1 to 3 days.[230] The onset of rotavirus disease is often abrupt, with fever and vomiting followed by explosive, watery diarrhea.[249,405,475] Vomiting may precede the diarrhea in approximately half the cases. Stools are nonbloody and generally lack fecal leukocytes, but mucus may be found in 20 percent. The disease is usually self-limited, lasting 4 to 8 days, although the duration of symptoms ranged between 2 and 22 days in a Guatemalan study.[521] In a cohort study in children with symptomatic disease, 62 percent had mild disease, 35 percent had moderate disease, and 3 percent had severe disease; 7 percent of children required hospitalization.[393] In another study, 64 percent of children with rotavirus diarrhea had vomiting, 64 percent had fever, 14 percent were dehydrated, and 18 percent were hospitalized.[372] About two thirds of children hospitalized with rotavirus disease will have diarrhea, vomiting, and fever, but children may also have only one or two of these symptoms.[445] When hospitalization is required, the stay usually is brief, with an average of 4 days and a range of 2 to 14 days.[405] Recovery generally is complete, but persistent diarrhea associated with lactose intolerance has been described.[25,267] Complications and death are generally due to dehydration, electrolyte imbalances, and acidosis.

In general, rotavirus infections are more severe than those caused by other viral gastrointestinal agents and therefore are more likely to result in hospitalization.[42,405] In developing countries, 20 to 40 percent of hospitalizations for diarrhea are due to rotavirus infections,[125,222,319,324] whereas in the United States, rotavirus is estimated to account for between one third and two thirds of admissions for diarrhea in children.[406] Vomiting, dehydration, and hospitalization occur significantly more often in patients infected with rotavirus than in those with other causes of diarrhea.[405,475] In one study, vomiting and diarrhea also lasted longer in patients infected with rotavirus (2.6 vs. 0.9 days and 5.0 vs. 2.6 days, respectively).[405] In another study, the severity score for rotavirus diarrhea was almost twice that of disease having other causes.[412] In one study, children with acute gastroenteritis due to rotavirus compared with children who were rotavirus negative were significantly more likely to have a severe clinical score (68% vs. 32%), to be severely dehydrated (63% vs. 37%), and to receive rehydration therapy (56% vs. 33%).[289]

The peak viral shedding in stools occurs on about day 3 of illness.[496] In a study evaluating shedding by PCR, the duration of rotavirus shedding ranged from 4 to 57 days in hospitalized patients.[399] Approximately half of the children shed for fewer than 10 days and 70 percent for fewer

*References 94, 158, 207, 291, 365, 382, 506.
†References 113, 169, 262, 270, 295, 391, 512.

than 20 days. In a study conducted in Guatemala, prolonged viral shedding was reported for as long as 5 weeks.[290] Prolonged shedding has been reported in children with immunocompromised states.[426]

Laboratory findings are related mostly to the extent of dehydration and can include elevated blood urea nitrogen and evidence of mild metabolic acidosis. In children with dehydration caused by rotavirus, dehydration was more likely to be isotonic than was dehydration caused by other agents in one study,[405] whereas in another study, one fourth of the patients infected with rotavirus presented with hypernatremic dehydration.[249] In a study examining the complications of community-acquired rotavirus in hospitalized children, of the 723 children in the study, 1.7 percent had severe dehydration requiring intensive care, 9.1 percent had hypertonic dehydration, 4.0 percent had seizures, and 0.1 percent died.[221]

Symptoms and viral shedding in children with rotavirus disease can be prolonged in immunocompromised patients either as a result of primary immunodeficiencies or from bone marrow or solid-organ transplantation.* More severe infection has not been seen in children with human immunodeficiency virus (HIV) infection.[239,448]

Other clinical manifestations associated either etiologically or incidentally with rotavirus infection have been described. Necrotizing enterocolitis has also been associated with rotavirus,[127] but the possibility of false-positive reactions obtained with some ELISA tests in neonates must be considered. Rotavirus antigen and infectious virus have also been reported in the blood of immunocompetent children with confirmed rotavirus gastroenteritis.† Most children infected with rotavirus have been viremic, independent of the presence of diarrhea. Central nervous system involvement was first associated with rotavirus infections by use of electron microscopy and antigen detection methods in children with aseptic meningitis[476,519] and encephalopathy.[231] However, more recently, cases have been reported by identification of rotavirus RNA in the cerebrospinal fluid with use of RT-PCR analysis. Rotavirus RNA has been found in the cerebrospinal fluid in rotavirus-infected children with seizures,[279,331,344,347] encephalitis,[167,197,279,328,530] encephalopathy,[134,167,284] and flaccid paralysis.[87] Of the 23 cases described, 15 were reported to have full recovery, whereas 6 had significant neurologic complications and 2 children died.

The relationship between intussusception and natural rotavirus infection is of great interest because of the reported link between the tetravalent RRV vaccine and intussusception (discussed in the section on vaccines).[71,75,241] Several studies have investigated the possible infectious etiology of intussusception.‡ Given the rarity of intussusception, these studies have had small sample sizes, they have typically been case series, and a number of different pathogens have been identified. Adenoviruses have been identified most often. Whereas the lack of seasonal variation for intussusception may suggest that wild-type rotavirus does not cause intussusception,[78,398] the possibility remains that many intestinal pathogens, including rotavirus, may cause intussusception, and multiple agents may account for the lack of seasonality. Three case-control studies, however, did not find an association with wild-type rotavirus and intussusception.[20,37,480]

TREATMENT

Treatment of rotavirus gastroenteritis is aimed largely at restoration of the proper fluid balance in dehydrated patients.[235] Continuation or early reintroduction of oral feeding is important. Breast-fed infants should continue to be breast-fed and formula-fed infants should continue with their usual formula after being rehydrated.[235] Emphasis has shifted from intravenous rehydration to oral rehydration with glucose-electrolyte solutions.[323] The glucose in the solution enhances sodium and therefore water absorption in the intestine. Several studies have shown the utility of this approach for treatment of rotavirus gastroenteritis.[414,421,422] The solution accepted by the World Health Organization contains 30 mEq/L of sodium, 30 mEq/L of potassium, and 30 mEq/L of bicarbonate, which is similar to other oral rehydrating solutions available commercially. Should oral rehydration efforts fail or in cases of severe dehydration and shock, fluid should be administered intravenously.

Other experimental approaches to treatment are based on the success of passive oral therapy in animals. Chronic rotavirus shedding has been treated successfully in immunocompromised children with human milk that contained rotavirus antibody.[426] Similarly, immune colostrum, immunoglobulin, or milk from rotavirus-immunized cows and human immunoglobulin have had some success.[122,184,195,311,425] A Cochrane Review, however, did not find sufficient evidence to warrant use of oral immunoglobulin in low-birth-weight infants.[345,346] A hyperimmune immunoglobulin Y (IgY) was evaluated in a randomized placebo-controlled trial in pediatric patients with rotavirus-associated diarrhea.[388,423] Children who received the IgY had significantly lower mean oral rehydration fluid intake, mean duration of intravenous fluid administration, mean duration of diarrhea, and mean duration of rotavirus clearance from the stool compared with placebo.[388]

Trials of bismuth subsalicylate have also been conducted and demonstrated a shortened duration of illness.[146,443,444] Probiotics have been shown to have beneficial albeit modest effects.[183,185] The use of probiotics has been shown to decrease rotavirus shedding in one study[144] and in a meta-analysis was shown to reduce the duration of diarrhea by about one day.[8] The effectiveness of probiotics appears to be strain and dose dependent.[185] In a comparative trial, both a single-species product and one with four strains were found to decrease the duration of diarrhea compared with oral rehydration alone.[173] In another trial, zinc plus a probiotic was found to decrease the length of hospitalization.[117]

Racecadotril (acetorphan), an enkephalinase inhibitor with antisecretory and antidiarrheal properties that

*References 140, 164, 224, 266, 394, 426, 450, 451.
†References 43-45, 83, 147, 354, 389, 390.

decreases intestinal hypersecretion but not motility by preventing the breakdown of endogenous enkephalinase in the gastrointestinal tract, has been shown to be effective in the treatment of diarrhea in adults and children.[194,261,418] In one study, oral treatment with racecadotril decreased stool output up to 50 percent in children with watery diarrhea.[76] A similar decrease was seen in boys with rotavirus infection.[418] Another drug, nitazoxanide, licensed for treatment of *Giardia intestinalis* and *Cryptosporidium parvum* infections, has shown some effectiveness in treatment of rotavirus infection.[43,461] In one study, 7.5 mg/kg of nitazoxanide administered orally twice a day for 3 days reduced the duration of illness in children with rotavirus gastroenteritis from 75 hours to 31 hours.[43]

VACCINES

The development of rotavirus vaccines has been a major priority because of the high burden of disease, and cost-effectiveness analyses have shown that a rotavirus immunization program would be cost-effective from the perspective of society and the health care system.[514,517] Because natural rotavirus infections induce excellent protection against severe rotavirus disease, vaccine efforts have been largely directed at the development of live attenuated rotavirus vaccines. However, there is still a continued interest in killed vaccines, primarily because of the reduced efficacy seen in resource-poor countries.[217,355]

Whereas the development of rotavirus vaccines has had a relatively short time line, there have been several obstacles to overcome. Just 10 years after the identification of rotavirus as an agent of severe diarrhea, the first vaccine trials were conducted.[485] Efforts initially concentrated on the use of animal rotavirus strains, labeled the Jennerian approach[228] because it relies on the natural attenuation of animal viruses in humans for safety or the attenuation of human strains. The initial efforts with bovine rotavirus vaccines RIT 4237[124,423,483,484] and WC3[32,307] and rhesus monkey vaccines RRV[150,282,397,423,493] and MMU 18006[396] yielded inconsistent results. Therefore, in an attempt to make the vaccines more closely related to human strains, human rotavirus genes coding for the proteins that induce neutralizing antibody VP7 or VP4 were introduced into these animal strains by creating reassortant viruses as described earlier. The segmented genome of rotavirus renders production of these reassortant rotaviruses relatively easy. Reassortant vaccines were developed with RRV[306,308] and WC3[32,91,471] and later UK[229,491] as the animal strain. This approach ultimately produced the first licensed rotavirus vaccine, RotaShield,[1,329] and one of the two currently licensed rotavirus vaccines, RotaTeq.[2,348] The attempt to develop rotavirus vaccines with use of attenuated human strains began with the neonatal human viruses M37 and RV3 that were thought to be naturally attenuated.[23,149,495] The attenuation of a human strain resulted in the licensure of the other rotavirus vaccine now licensed for use, Rotarix.[3,101]

Past and Currently Licensed Rotavirus Vaccines (Fig. 172-3)

RotaShield

History and Development of RotaShield. The development of RotaShield, a reassortant vaccine based on rhesus monkey rotavirus, began with evaluations of RRV. RRV replicates well in humans but produced mild side effects, including low-grade fever and mild diarrhea, especially when it was given to older children who had lost maternal antibodies.[276,371,486] Protection with this vaccine was inconsistent, ranging from greater than 50 percent, even in developing countries,[150,282,396] to moderate (20% to 50%),[397,493] to no protection.[88,423] Therefore, reassortants were developed containing the VP7 genes of G1, G2, or G4 serotype and the 10 other genes from RRV. The G3 serotype representative for the RRV tetravalent vaccine (RRV-TV) was RRV. Thus, four of the common VP7 serotypes were incorporated into the vaccine. Vaccination produced a rotavirus IgG and IgA serum antibody response, but neutralizing antibodies were produced predominantly to RRV rather than to the human serotypes.[28,369,395] This finding appears to be consistent with the experiments showing that VP4 rather than VP7 is more immunogenic after natural infection.[508,510]

Safety and Efficacy of RotaShield. Extensive evaluations of RRV-TV were completed before licensure.[220,372,395] In a large trial conducted at centers across the United States,[395] the vaccine was found to be safe; however, the number of subjects with fever after the first dose was increased compared with children receiving placebo. The vaccine was found to be effective and had the highest

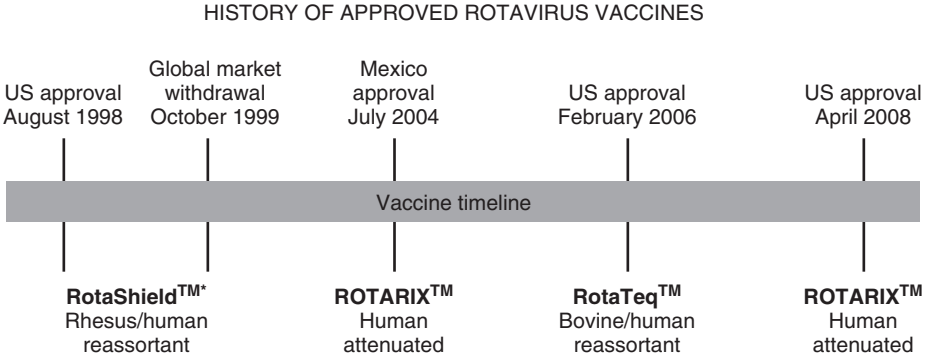

FIGURE 172-3 ■ Time line of first approvals for rotavirus vaccines.

efficacy against more severe disease. Similar results were reported from Finnish studies, except that fever occurred somewhat more commonly and efficacy was somewhat enhanced.[220]

Post-Licensure Effectiveness and Safety. For these reasons, the RRV-TV vaccine, RotaShield, was licensed in the United States in 1998 and recommended for general use in all infants.[1] However, less than 1 year after licensing, 15 cases of intussusception occurring shortly after vaccination were reported to the Vaccine Adverse Events Reporting System.[71] Subsequent analyses led the American Academy of Pediatrics and the Advisory Committee on Immunization Practices to conclude that an association existed between receipt of the vaccine and the development of intussusception and to withdraw the recommendation for use.[4,75] The vaccine was therefore withdrawn by the manufacturer.

The initial publication describing the association reported an increased risk for development of intussusception from 3 to 14 days after receipt of the first dose of vaccine (adjusted odds ratio, 21.7).[318] A smaller risk also existed after receipt of the second dose of vaccine. Researchers estimated that one case of intussusception attributable to vaccination with RRV would occur for every 4670 to 9474 infants vaccinated. Ecologic studies that followed reported a lower vaccine-attributable risk.[317,437] The exact excess burden of intussusception during the life of the child has yet to be defined, but the best estimates are 1 per 10,000 to 12,000.[241,251,376,437] Further analysis revealed that the risk was age related and substantially increased in those older than 90 days.[409,438] The pathogenic mechanism for this association has yet to be defined.[280] The relationship between wild-type rotavirus infection and intussusception is unclear and is discussed in the clinical section.

Despite the withdrawal of RotaShield due to the association with intussusception, the vaccine was found to be effective. In one study, RotaShield was 100 percent effective (95% CI, 75%, 100%) in preventing hospitalization due to rotavirus in children receiving three doses of vaccine. When two doses of vaccine were given, the vaccine was also 100 percent effective (95% CI, 62%, 100%), whereas one dose was 89 percent effective (49%, 97%). A second vaccine effectiveness study in a pediatric practice setting yielded similar results.[375]

RotaTeq (RV5)

History and Development of RotaTeq. The development of RotaTeq began with evaluations of WC3 rotavirus vaccine. WC3 is of bovine origin and appeared to be free of side effects. It replicates poorly in humans, but infants develop a neutralizing antibody response to WC3 and both rotavirus IgA and IgG antibody.[32] The initial studies conducted in Philadelphia appeared promising,[90] but later trials in Cincinnati[52,204] and in less developed countries[162] did not show significant protection. WC3 was therefore used to make reassortants containing rotavirus genes encoding the VP7 and VP4 proteins of human serotypes, which became RotaTeq.

After the WC3 vaccine was shown to be safe but not consistently effective,[32,162] a monovalent vaccine containing the VP7 protein of a human G1 rotavirus was developed. This vaccine was reported to be effective especially against more severe disease during a predominantly serotype G1 outbreak in Rochester.[471] Next, a WC3-based reassortant quadrivalent vaccine including both VP7 and VP4 human rotavirus gene substitutions with G1, G2, G3, or P[8] substitutions and most other segments from WC3 was evaluated. In studies conducted at multiple centers in the United States, this vaccine was shown to be safe and effective against all cases of rotavirus gastroenteritis (75%) and especially against severe cases (100%).[89] In the multiple trials of WC3 and WC3 reassortant vaccines, the viruses replicated less well than RRV and did not induce fever as was noted with RRV and RRV reassortants.

Safety and Efficacy of RotaTeq. The final WC3 reassortant vaccine developed, the pentavalent RotaTeq vaccine, contains five different viruses: one each containing the VP7 of G1, G2, G3, and G4 human rotaviruses and one containing the most common VP4 (P8) gene (Fig. 172-4).[95]

The large pivotal trial of RotaTeq was conducted in more than 70,000 infants in 11 countries. It showed that the vaccine was effective and safe and, unlike RotaShield, did not induce fever.[492] Most important, there was no association with intussusception. Intussusception occurred in six vaccine recipients and five placebo recipients within 42 days after any dose (relative risk, 1.6; 95% CI, 0.4 to 6.4). The vaccine was also highly effective, reducing all G1-G4 rotavirus gastroenteritis by 74.0 percent, severe gastroenteritis by 98.0 percent, and hospitalizations and emergency department visits by 94.5percent. Type-specific efficacy against hospitalization and emergency department visits for rotavirus infections was as follows: G1, 95.1 percent; G2, 87.6 percent; G3, 93.4 percent; G4, 89.1 percent; G9, 100 percent; and G12, 100 percent.

Since the pivotal trial was published, multiple trials of RotaTeq have been conducted around the world.[219] Efficacy has been shown to be sustained for up to 3 years.[487,488] Safety and efficacy were also reported for premature infants.[171] As has been apparent for all rotavirus vaccines, the vaccine appears to be less effective in less developed areas of the world (Fig. 172-5).[17,433,534,535] In the most resource-poor settings, such as Africa and Asia, efficacy has been only 40 to 50 percent in clinical trials.[17,534,535] In general, this correlates with the lower immune response in these settings.[16,535] The reasons for this decrease are not well understood. Possible contributing factors include higher levels of transplacental and breast milk antibody that could inhibit vaccine virus replication, malnutrition, micronutrient deficiencies, interfering gut flora, and differences in the epidemiology.[355] One study evaluated the safety of RotaTeq in HIV-infected and noninfected infants in Kenya and found no significantly increased serious adverse events in HIV-infected children compared with those without infection.[259] However, given the small sample size in the study, there was not sufficient power to fully assess safety in this study.

Post-Licensure Effectiveness and Safety. The effectiveness of RotaTeq vaccine has been substantial wherever

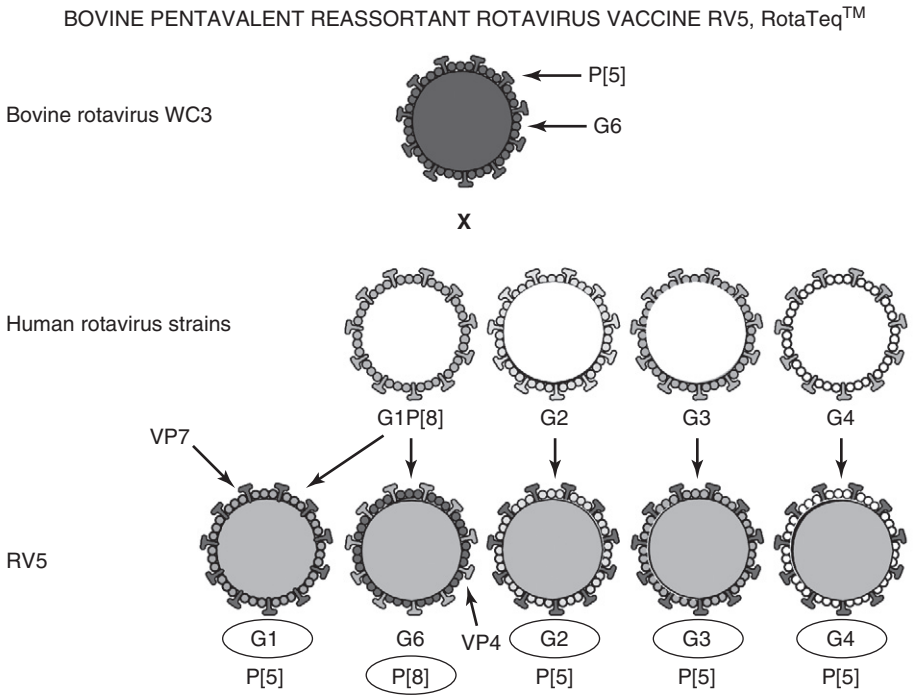

FIGURE 172-4 ■ RotaTeq is composed of five reassortant viruses: one each containing the VP7 of G1, G2, G3, and G4 human rotaviruses and one containing the most common VP4 (P8) gene. The remaining gene segments are derived from the bovine WC3 strain of rotavirus.

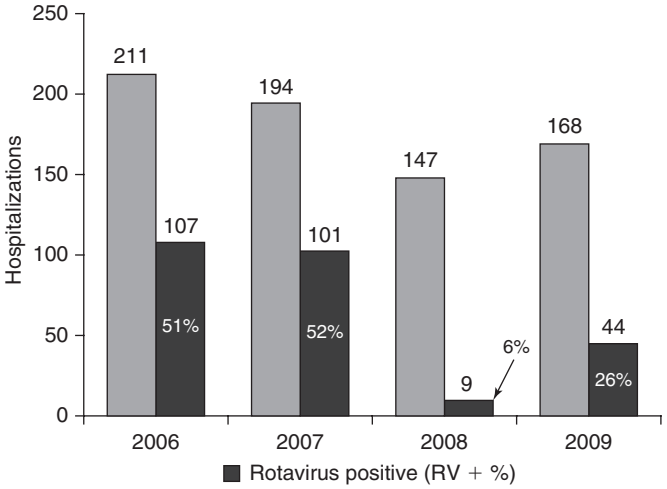

FIGURE 172-5 ■ Impact of rotavirus vaccines in the United States. The number and proportion of hospitalized children younger than 3 years with acute gastroenteritis who tested positive for rotavirus are shown by year from the New Vaccine Surveillance Network.

it has been evaluated.[163,170] Surveillance studies and laboratory monitoring conducted in the United States have shown remarkable reductions in rotavirus disease every year since vaccine introduction (Fig. 172-5).* In fact, in 2009-2010, the threshold for defining a rotavirus season was never achieved.[457] What has been particularly remarkable is the magnitude of the indirect or herd effects observed.[10,274,364] In 2008, shortly after vaccine licensure, reductions of rotavirus disease were seen not only in age-eligible vaccine recipients but in older children as well.[364] Rates of hospitalization for rotavirus gastroenteritis were reduced 87 percent in the 6- to 11-month age group (coverage, 77%), 96 percent in the 12- to 23-month age group (coverage, 46%), and 92 percent in the 24- to 35-month age group (1% coverage). Recent data further suggest that benefits in even older children and adults will be seen.[10,274] Post-licensure vaccine effectiveness studies have shown high levels of protection provided after each dose.[48,49,137,446,499] The large multicenter U.S. study found the effectiveness of RV5 against rotavirus-associated hospitalizations and emergency department visits to be 73 to 74 percent for one dose and similar at 88 percent and 85 to 87 percent for two and three doses, respectively, depending on the comparison group used.[446] In two post-licensure studies conducted in Nicaragua, the three-dose effectiveness of RV5 against severe disease ranged from 58 to 87 percent, depending on the control group chosen for comparison and the definitions used for severity.[288,353]

Monitoring for safety, including intussusception, has been in place since licensure, and the safety of RotaTeq vaccine continues to be monitored in the United States and abroad.* Whereas most studies have found no increased risk of intussusception to date, in one Australian study, there was an excess risk of intussusception in infants 1 month to younger than 3 months of age at 1 to 7 days (relative risk, 5.3) and 1 to 21 days (relative risk, 3.5) after dose one,[63] which is less than was seen in studies of RotaShield. Safety monitoring will continue to

*References 74, 107, 364, 456, 457, 459.

*References 63, 133, 142, 277, 434, 526, 538.

determine if an increased risk of intussusception exists in other countries, including the United States, although, given the large number of doses already used in the United States, any increased risk of intussusception would have to be low.

Rotarix (RV1)

History and Development of Rotarix. Rotarix, the other licensed rotavirus vaccine, is a live oral vaccine based on the attenuated human strain 89-12. Strain 89-12 is a G1P[8] virus, initially obtained from an infant with rotavirus gastroenteritis in Cincinnati, Ohio.[33] The isolate was attenuated by multiple passages in tissue culture; thus all genes are of human origin (Fig. 172-6). Results of the initial multicenter efficacy trial showed that two doses of this vaccine provided 89 percent protection against any rotavirus disease and 100 percent protection from more serious disease.[30]

The 89-12 strain was then purified by limiting dilution and further passaged in tissue culture. The final product, initially called RIX 4414 and later marketed as Rotarix, was evaluated in many studies. Reports from Singapore,[379] Finland,[490] Latin America,[269,411,419] and the United States[129] confirmed the safety and immunogenicity of the vaccine. In the initial efficacy trial of RIX 4414 conducted in Finland over two rotavirus seasons, the vaccine was 72 percent protective against all rotavirus gastroenteritis and 85 percent protective against severe gastroenteritis despite the relatively low dose of vaccine used.[490]

Safety and Efficacy of Rotarix. As with RotaTeq, Rotarix was evaluated in a large safety and efficacy trial. In a study of more than 63,000 infants conducted primarily in several countries in Latin America, the vaccine was found to be effective and safe.[411] The vaccine did not induce fever and, most important, was not associated with intussusception. During the 31-day window after each dose, six vaccine recipients and seven placebo recipients had definite intussusception with no evidence of clustering. Over the duration of the study, there were 16 cases of intussusception in the placebo group compared with 9 in the vaccine group.

In this large study, efficacy was 84.7 percent against severe rotavirus gastroenteritis and 85 percent against rotavirus-related hospitalizations. Efficacy was 91.8 percent against G1[P8] strains and 87.3 percent against the VP4-related G3P[8], G4P[8], and G9P[8] strains. Efficacy against G2P[4] strains in the few subjects infected with these viruses was lower (41.0%).

In a trial of 3994 infants conducted in six European countries, a population more similar to that used for evaluation of RotaTeq, protection was 78.1 percent against rotavirus of any severity, 90.4 percent against severe rotavirus gastroenteritis, and 96 percent against hospitalization due to rotavirus during the combined follow-up period.[489] There was a slightly higher efficacy of 87.1 percent against any severity, 95.8 percent against severe rotavirus, and 100 percent against rotavirus-associated hospitalizations. Efficacies against severe disease due to G3 (93.7%), G4 (95.4%), and G9 (85.0%) rotaviruses were similar to efficacy against G1 (96.4%), and the efficacy against the G2 strain was 85.5 percent.

Because Rotarix is a monovalent G1[P8] vaccine and contains neither G2 nor G9 [P4], there has been interest in examining the efficacy of Rotarix against heterologous strains such as G2[P4] and G9[P4]. In an integrated analysis, efficacy during the combined study period against G2[P4] was 58.3 percent against disease of any severity and 85.5 percent against severe disease.[128,489] More recently, a study in Mexico showed efficacy of 94 percent against rotavirus hospitalizations due to a fully heterotypic G9P[4] rotavirus strain in Mexico.[523] In addition, high rates of efficacy against severe rotavirus disease due to G1 (100%) and non-G1 (94.9%) types were demonstrated in a trial in Singapore, Hong Kong, and Taiwan during a 3-year follow-up period.[378]

When trials of Rotarix have been conducted in resource-poor countries, efficacy has been decreased, similar to what has been reported for RotaTeq (Fig. 172-7). For example, in a study of African infants, overall efficacy against severe disease was 61.2 percent, but it was even lower in infants from Malawi (49.4%) compared with South African infants (76.9%).[281] Despite the lower efficacy seen for both vaccines in these poorer countries, the impact of rotavirus vaccines is still substantial in that more lives can be saved in countries with high rotavirus mortality even with the decreased efficacy of these vaccines. Thus, in the example, more lives would be saved in Malawi compared with South Africa despite the lower efficacy of the rotavirus vaccine in Malawi.

Post-Licensure Effectiveness and Safety of Rotarix. The effectiveness of Rotarix has been verified in several studies.[219,334] In El Salvador, a low- to middle-income country, effectiveness was 76 percent against rotavirus hospitalization.[126] In Brazil, effectiveness was 77 percent against rotavirus hospitalizations or emergency department treatments.[106] Effectiveness was markedly reduced in those older than 12 months. Of interest, in a G9 rotavirus outbreak in Australia, effectiveness was 85 percent.[439] Perhaps most important, vaccination has been associated

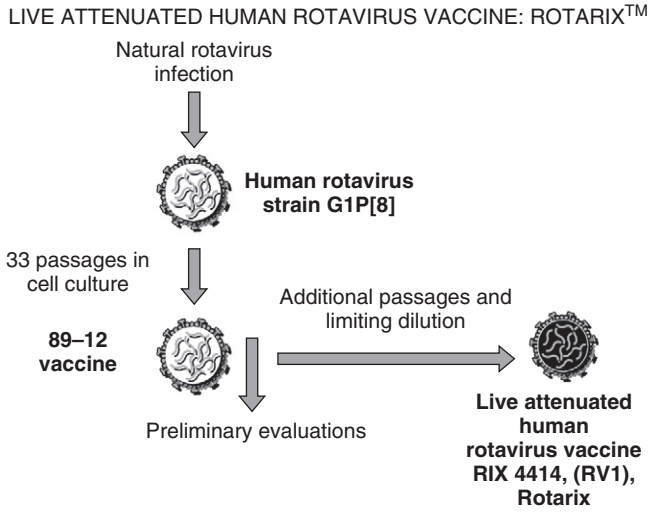

FIGURE 172-6 ■ Rotarix was derived from a human G1P[8] strain obtained from an infant with rotavirus disease. It was passaged 33 times in tissue culture and then evaluated as strain 89-12. After initial studies indicated it was safe and effective, it was purified by limiting dilution and evaluated further as RIX 4414.

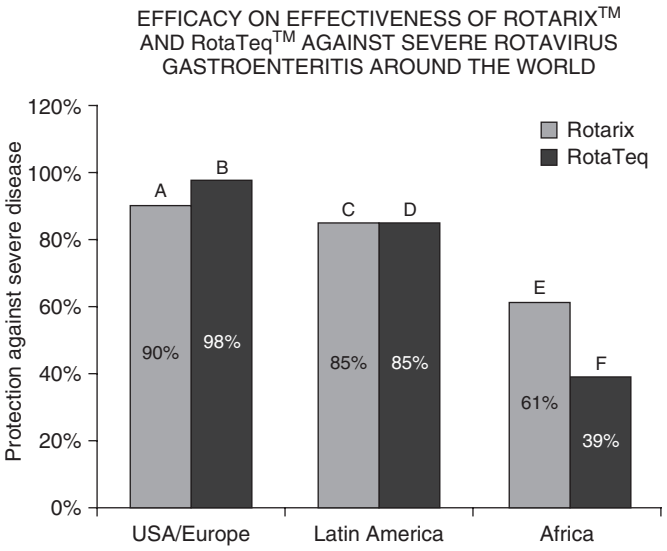

FIGURE 172-7 ■ The efficacy of rotavirus vaccines differs remarkably around the world, decreasing as the socioeconomic conditions decline. Selective studies include Vesikari et al,[489,492] Ruiz-Palacios et al,[411] Mast et al,[288] Madhi et al,[281] and Armah et al.[17]

with reduced mortality from diarrhea-associated disease. In a study in Mexico,[400] diarrhea-related mortality fell from an annual median of 18.1 deaths per 100,000 children younger than 5 years before the introduction of Rotarix vaccination to 11.8 per 100,000 children in 2008 (about 2 years after introduction of the vaccine). Among infants who were 11 months of age or younger, diarrhea-related mortality fell from 61.5 deaths per 100,000 children at baseline to 36.0 per 100,000 children in 2008. These findings were recently extended to show reductions for 3 full years.[401]

Subsequent to licensure and widespread use, several studies evaluating intussusception have been reported. Studies conducted in Mexico and Brazil[357] revealed an increase rate within 7 days after the first dose in Mexico, whereas in Brazil there was no increase after the first dose but a small increase after the second dose. Overall, there was an increased rate of intussusception of about 1 per 51,000 infants in Mexico and 1 per 68,000 infants in Brazil. The authors concluded that "the absolute number of deaths and hospitalizations averted because of vaccination far exceeded the number of intussusception cases that may have been associated with vaccination." In an Australian study that evaluated both RotaTeq and Rotarix, there was an increased relative risk for intussusception of 3.5 and 1.5 for the 1 to 7 days and 1 to 21 days after Rotarix immunization, respectively, in infants 1 month to younger than 3 months of age.[63] At this time, there has not been sufficient time in the United States to assess the risk for intussusception with Rotarix after licensure.

Vaccine Schedule for Both Vaccines

RotaTeq is administered orally in a three-dose series, at ages 2, 4, and 6 months, with the first dose administered by 12 weeks with completion of the series by 32 weeks. Rotarix is administered orally in a two-dose series, at ages 2 and 4 months. Rotarix requires administration of the first dose by 20 weeks and completion of the series by 24 weeks. To simplify and harmonize the schedules, the Advisory Committee on Immunization Practices recommended administration of the first dose of either vaccine by 14 weeks, 6 days and completion of the series by 8 months, with a minimum interval of 4 weeks between doses.[108]

Other Safety Issues for Both Licensed Vaccines

Transmission of Vaccine Virus

Both licensed rotavirus vaccines are live attenuated vaccines and are therefore able to replicate in the intestine of the vaccinee and to be shed in the stool.[379,524] Transmission of both Rotarix in a study of twins[404] and a reassortant virus derived from RotaTeq[361] has been documented.

Porcine Circovirus

In 2010, nucleic acids from an adventitious virus were identified in Rotarix during evaluations of novel viral detection techniques.[497] The detected virus shared 98 percent identity to porcine circovirus (PCV) 1 and included the complete genome. PCV commonly infects pigs; it has been reported to be detected in 5 percent of stool samples from U.S. adults and is thought to be due to dietary consumption of pork products.[497] PCV is not believed to cause illness among humans.[253,264,497] In early 2010, this finding was reported to the U.S. Food and Drug Administration (FDA), which led to the temporary suspension of Rotarix even though there was no evidence of any safety risk.[73] Shortly thereafter, the FDA reported preliminary findings that RotaTeq also contained detectable PCV material from both PCV-1 and PCV-2. Subsequently, on the basis of the available evidence regarding a theoretical risk of PCV infection among humans compared with the observed benefits of rotavirus vaccines in preventing severe acute gastroenteritis among infants, the FDA recommended that clinicians resume use of Rotarix and continue to use RotaTeq.[253] Further investigation suggested that PCV material had been introduced into both rotavirus vaccines through porcine-derived trypsin. This reagent was used in the cell culture growth process of vaccine production, which commenced several years before randomized, controlled, multicenter phase III clinical vaccine trials were conducted for either vaccine.[154,392]

NON-LIVE VACCINES

Because live oral rotavirus vaccines have been much less immunogenic and effective among infants in resource-limited settings, there is continued interest in non-live vaccines. Preclinical studies have included the use of virus-like particles[104,333] that appeared to be protective in mice but not in pigs,[531] DNA vaccines,[82,86] and subunit vaccines, including VP7, VP4, and VP6.[85,500] The

excellent protection in mice, particularly with virus-like particles or VP6 protein, remains to be verified in human studies. The immunogenicity and protection of a candidate inactivated rotavirus vaccine, human strain CDC-9 (G1P[8]) formulated with aluminum phosphate, were also recently evaluated in gnotobiotic piglets. The vaccine was immunogenic and protected animals after oral challenge with a homologous virulent human strain Wa (G1P[8]).[501] It remains to be seen whether these strategies will have a role as alternative approaches.

SUBSECTION 4 *TOGAVIRIDAE*

CHAPTER 173

RUBELLA VIRUS

James D. Cherry • Kristina Adachi

Rubella (German measles) is a generally mild, exanthematous, infectious illness in which morbidity and mortality in children usually are minimal. However, infection in pregnancy may result in fetal infection, which usually is associated with considerable adversity for the developing infant. The rubella virus has only one known type.

HISTORY

In ancient history, rubella as a disease is lost among the other prominent exanthematous diseases (e.g., scarlet fever, measles, and smallpox). In an extensive review, Griffith[229] suggested that rubella was known to the early

Arabian physicians under the name *al-hamikah;* they considered rubella a form of measles, however. Two German physicians, de Bergen in 1752 and Orlow in 1758, usually are credited with providing the first clinical descriptions of rubella as a specific entity.[229,607] In early writings, rubella generally was called *Röteln.*[182,607] However, because of the great interest of German physicians in the disease during the period from the mid-18th to the mid-19th centuries, the name *German measles* frequently was used in other countries.

In 1866, a Scottish physician named Veale[584] described 30 cases of German measles. In his paper, he gave the illness its present name, *rubella*. His opinion was that the German name Röteln was too harsh and foreign and that other possible names—*rubeola notha* and *rosalia idiopathica*—were too long for general use and could be confused with measles.[183] Other historical synonyms of rubella include rubeola, rubeola sine catarrho, rubeola epidemica, rubeola morbillosa, rubeola scarlatinosa, rosania, roseola, roseola epidemica, rosalia, scarlatina morbillosa, scarlatina hybrida, morbilli scarlatinosi, feuer masern, roséole, roséole idiopathique, rubéole, rougéole fausse, French measles, false measles, bastard measles, hybrid measles, and bastard scarlatina.[229]

In 1881, at the International Congress of Medicine in London, a consensus was reached that rubella is a distinct disease. Rubella was thought to be similar in some respects but not identical to measles or scarlatina. By the beginning of the 20th century, the clinical description of rubella was complete, except that joint manifestations had received curiously little notation.*

Rubella gained its present-day importance in 1941 when Gregg,[228] an Australian ophthalmologist, reported congenital defects in babies of mothers who had rubella during early pregnancy. In spite of considerable skepticism, Gregg's observations were confirmed quickly by Swan and colleagues[549,550] in Australia and other investigators in the United States and the United Kingdom.[164,459,466,607] By 1947, 28 communications describing 500 children with severe congenital defects associated with maternal rubella had appeared in the literature.[607]

In 1938, Hiro and Tasaka[269] demonstrated that rubella is a disease of viral etiology by transmission of disease to humans through the subcutaneous injection of filtered nasal washings. In 1942, Habel[237] was able to infect monkeys with nasal washings and blood from human cases. In 1962, rubella virus first was propagated in the laboratory; two investigative teams, Weller and Neva[606] and Parkman and colleagues,[422] using different techniques, reported the growth of rubella virus in tissue culture.

The isolation of rubella virus in 1962 paved the way for definitive study of the 1964 rubella pandemic.[358,422,606] The results of extensive virologic, serologic, and epidemiologic investigation were presented at a Rubella Symposium in May 1965.[319] After the rubella virus was isolated in tissue culture, an intensive worldwide effort to develop vaccines was mounted. The accumulation of these experiences resulted in an extensive body of knowledge related to rubella and rubella immunization that was presented at the International Conference on Rubella Immunization in February 1969.[320] Live attenuated rubella virus vaccines were licensed for use in mid-1969 in the United States.[317,371,603] In the 38-year period since vaccine licensure and its universal use in the United States occurred, the yearly occurrence of rubella fell from 40,000 cases to 11 cases in 2005.*

At present, sustained transmission of rubella no longer occurs in the United States.[86,455]

PROPERTIES

Classification

Rubella virus is placed in the *Rubivirus* genus of the family *Togaviridae*.[174,495,618] At present, it is the only species in this genus. The virus is similar physiochemically to the other member of its family (alphavirus) but is unrelated serologically. Rubella virus has no invertebrate host (a characteristic of all alphaviruses), and humans are the only known vertebrate host.

In 2005, the World Health Organization (WHO) adopted a systematic nomenclature to categorize the distinct genetic variants of rubella virus. Rubella virus genotypes were divided into 2 phylogenetic groups, Clade 1 and Clade 2, differing by only 8 to 10 percent at the nucleotide level. Clade 1 includes 10 genotypes (1a, 1B, 1C, 1D, 1E, 1F, 1G, 1h, 1i, and 1j), and Clade 2 includes 3 genotypes (2A, 2B, and 2C). Recognized genotypes are denoted with uppercase in contrast to provisional genotypes designated with lowercase letters. Of these 13 genotypes, only 3 (1E, 1G, and 1B) are noted to have a large global distribution. This classification has been especially important in the WHO's virologic surveillance and has greatly aided elimination efforts.[2,623]

Physical Properties

The rubella virion is spherical, with a diameter of 60 to 70 nm, and consists of a capsid protein (C) and two glycoproteins (E1 and E2).† E1 (relative molecular weight, 58,000) and E2 (relative molecular weight, 42,000 to 47,000) are glycosylated and are located on the viral surface membrane. E1 is the viral hemagglutinin that is found on 5- to 6-nm surface projections.[272,431] The nucleocapsid has a diameter of 30 to 40 nm and is composed of a polypeptide (C protein) and the genomic RNA. The nucleic acid of rubella virus is single-stranded RNA with a molecular weight of 3.2 to 3.8×10^7 and a genome of 9762 nucleotides.[505] Its genome encodes five protein products, including two nonstructural proteins (P90 and P150) and three virion proteins (the capsid, E1, and E2).[2] The outer coat of the virus (envelope) is lipoprotein with host-cell lipid and virus-specified polypeptides.

†References 94, 335, 354, 431, 495, 618.

Rubella virus is relatively sensitive to heat; it generally has been found to lose infectivity within 30 minutes at 56° C (132.8° F).[170,423,436] However, Kistler and Sapatino[309] observed that some infectivity persists even after heating for 60 minutes at 70° C (158° F). At 37° C (98.6° F) in the presence of 2 percent serum, 90 percent is inactivated in 3 hours.[423] At 4° C (39.2° F), with protein stabilization, viral titers are maintained for 7 or more days. The virus is stable indefinitely at –60° C (–76° F) and below but labile at normal (–10° to –20° C [14° to –4° F]) refrigeration temperatures. When it is stabilized with protein, the virus can survive several rapid freeze–thaw cycles without significant loss of titer.[489]

Rubella virus is sensitive to ultraviolet light. In 1 hour, a high-titer cell-free virus suspension was inactivated by an intensity of 1350 μW/cm^2; on the other hand, a tissue culture suspension of virus was not inactivated completely when it was exposed to a similar intensity of radiation.[309] Rubella virus is sensitive to visible light, and this photosensitivity can be potentiated by the basic dye proflavine.[50]

The virus also is sensitive to pH extremes of less than 6.8 and greater than 8.1.[91] The following chemicals rapidly inactivate rubella virus: ether, acetone, chloroform, deoxycholate, formalin, β-propiolactone, ethylene oxide, free chlorine, and 70 percent alcohol.[436] It is resistant to thimerosal.

Antigenic Composition

Rubella virus infection of tissue culture cells results in the production of infectious virus that can be neutralized by specific antiserum. Specific viral antibodies can be identified by hemagglutination inhibition (HI), complement fixation (CF), precipitation in gel, platelet aggregation, passive hemagglutination, single radial hemolysis, latex agglutination, enzyme-linked immunosorbent assay (ELISA), and immunofluorescence.* Neutralization and HI identify antibodies that inhibit specific biologic functions of the virus, whereas the other assays identify only the formation of antigen-antibody complexes. The E1 glycoprotein is the predominant erythrocyte-binding and neutralization site of the virus.[570,601] Weak neuraminidase activity also has been associated with purified rubella virus.[27]

In 1967, Stewart and associates[540] reported that tissue culture–grown rubella virus produced hemagglutination of erythrocytes from chickens that were younger than 1 day old and from one goose and one lamb, but no hemagglutination was observed with adult chicken, guinea pig, and other red cell preparations commonly used. Subsequently, techniques involving careful control of test system diluents have revealed that red cells from many different animals are agglutinated by rubella virus.[340,500] Viral hemagglutinin is stable at –20° C (–4° F) for months and at 4° C (39.2° F) for several weeks but is destroyed rapidly by heat.[202,241]

Sever and colleagues[515] first demonstrated that supernatant fluid from primary African green monkey kidney (AGMK) and rabbit kidney epithelial cells (RK-13) tissue cultures contained useful complement-fixing antigens. Two distinct rubella complement-fixing antigens exist.[501] One of the antigens is similar in size and weight to both the hemagglutinin and infectious virus; the other "soluble" antigen is smaller, with a buoyant density of 1.08 g/mL. The soluble antigen is noninfectious and does not contain nucleic acid.[436] Rubella complement-fixing antigens retain their antigenicity after either treatment.

Two major small-particle antigens have been identified in the medium of tissue culture–infected cells by immunodiffusion.[330,337,499] These two soluble antigens are structural components of the virion, and natural infection with rubella virus results in the formation of serum precipitating antibodies. These antigens have been designated *theta* and *iota*. Their importance lies in the fact that antibody to the iota antigen rarely is noted in the serum of recipients of some rubella vaccines; therefore, they may be of value in studying vaccine-induced immunity.[69,332]

The E1 glycoprotein is the dominant surface molecule of rubella virus.[95] It is the main target of the humoral antibody response for both detection and elimination of the virus. HI and neutralization sites have been localized to a small segment of the E1 glycoprotein ($E1_{245}$ to $E1_{285}$). A recent study identified the myelin oligodendrocyte glycoprotein (MOG) as the host cell receptor for the rubella virus that interacts with the E1 glycoprotein. Blocking this MOG attachment site of rubella virus may also prove to be a potential way to prevent rubella virus infection of cells.[114]

Seventeen T-cell epitopes have been identified with the lymphoproliferation assay.[94,384] They involve the capsid protein and E1 and E2 glycoproteins.

Molecular analysis of rubella virus epidemiology from 1961 to 1997 in North America, Europe, and Asia found no major antigenic variations.[195] Further phylogenetic analysis of a collection of 103 E1 gene sequences from rubella viruses isolated from 17 countries from 1961 to 2000 found the existence of at least two genotypes.[628] Previous work noted rubella genotype 1 isolates predominantly in Europe, Japan, and the Western Hemisphere, whereas genotype 2 isolates were limited to Asia and Europe. As noted earlier, in 2005, the WHO adopted new nomenclature to categorize all of the new genetic variants of rubella found.[2]

Tissue Culture Growth

Rubella virus grows in many different tissue cultures, including cell strains, cell lines, and primary cells.* Cell sources include mature and embryonic tissue from humans and other primates, rabbits, swine, dogs, birds, hamsters, and cattle. In tissue culture, growth of rubella virus can be identified by either its cytopathic effect or its ability to interfere with the growth of another tissue culture–susceptible virus.

The method used most commonly for primary isolation of rubella virus from clinical material is the

*References 132, 357, 360, 423, 436, 617, 618.

interference technique with primary AGMK cells.[422] In this system, nonadapted rubella virus grows readily but does not produce a cytopathic effect. Infection is demonstrated in AGMK tissue culture by the failure of a typical enterovirus cytopathic effect to occur after the culture is challenged with echovirus 11 or another suitable enterovirus. A common alternative to the AGMK–echovirus 11 interference system for primary isolation of rubella virus is use of the RK-13 cell line, in which infection can be identified by cytopathic effect. For laboratory study and determination of neutralizing antibody, many different cell lines (e.g., RK-13, baby hamster kidney cell [BHK]-21, and rhesus monkey kidney epithelial cells [LLC-MK2]) can be used. The highest titers of rubella virus are produced in the BHK-21 and Vero cell lines.

Kinetic studies in tissue culture indicate that virus adsorption is complete within 90 minutes and that the eclipse period lasts approximately 12 hours. The first new virus noted is cell associated; it is followed in 2 to 4 hours by extracellular virus. In primary cell culture, titers of both cell-associated and free virus reach 10^3 tissue culture infectious dose $(TCID)_{50}$/mL by the fourth day; peak titers are not attained until approximately the 17th day. In all cell systems, chronic infection occurs but is limited in some cultures by the cytopathic effect. Rubella virus induces the formation of plaques in several cell lines.

Animal Susceptibility

Although natural infection is known to occur only in humans, several other primates have been infected experimentally.[357,423,436] In addition to primates, rabbits, hamsters, ferrets, guinea pigs, and suckling mice have been infected with rubella virus.

EPIDEMIOLOGY

In contrast to measles and other diseases having clearly apparent dramatic cycles, knowledge of rubella epidemiology has been acquired primarily during the last 75 years. Major events during this period that stimulated interest in its epidemiology were the observation of teratogenicity in 1941,[228] the isolation of the virus in the early 1960s,[422,606] and the pandemic of 1964. Unfortunately, rubella was not a reportable disease in the United States until 1966, so considerable gaps exist in the available information. At present, we are in a new epidemiologic era because of the widespread use of rubella vaccine. Predicting the incidence of rubella today must take into account the extent and method of vaccine use in the population under surveillance.

Incidence and Prevalence

Epidemic Behavior

The epidemic pattern of rubella in selected areas of the United States in the prevaccine and early vaccine eras is presented in Figure 173-1. The number of reported cases of rubella and congenital rubella syndrome by year in the vaccine era is presented in Figure 173-2. The rubella epidemic cycle usually is described as one of 6- to 9-year intervals, with each cycle consisting of a build-up and fall in incidence during the course of a 3- to 4-year period.[279,280] However, a close look at Figure 173-1 suggests that the basic pattern in the prevaccine era was a 3.6-year cycle. Of the 11 peaks from 1928 to 1968, all but 2 occurred in a 2- to 4-year span, with a median of 3 years. Over and above the 3-year cycle is the better known 6- to 9-year cycle of major disease. Pandemics occurred in the periods 1941 to 1944 and 1963 to 1965.

The U.S. rubella pandemic of 1964 to 1965, which initially began in Europe in 1963, exemplifies the extent of morbidity that rubella has the potential to cause.[436] At that time, there were an estimated 12.5 million cases of rubella, including more than 2000 cases of encephalitis, 11,250 fetal deaths, 20,000 cases of congenital rubella syndrome, 3580 deaf-blind children, and 1800 children with mental retardation.[623]

Since the introduction and widespread use of rubella vaccine in the United States, epidemic rubella has occurred only once on a national scale (see Fig. 173-2).[84,85,454]

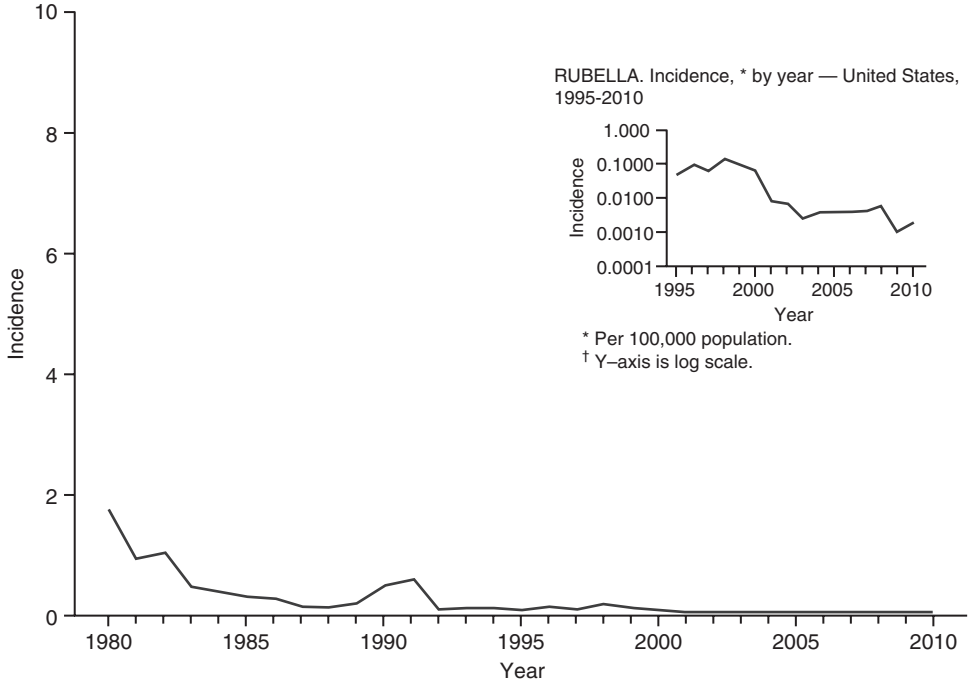

FIGURE 173-3 ■ Rubella. Incidence per 100,000 by year: United States, 1980-2010. (From Centers for Disease Control. Summary of notifiable diseases: United States, 2010. *MMWR Morb Mortal Wkly Rep* 2012;59:1–111.)

In 1991, 1401 cases of rubella and 47 and congenital rubella syndrome were reported.[87] At present, rubella virus is no longer circulating in the United States, and the cases that occurred in the more recent years were importations.[82,455]

In fact, on October 29, 2004, an expert review panel from the Centers for Disease Control and Prevention (CDC) declared that the rubella virus has not been an endemic threat since 2001 in the United States. Recent data collected from 2005 to 2007 has shown the annual incidence of rubella to be 0.005/100,000 population, with a median number of reported cases as 11, which were primarily import associated.[457] Data from the *Morbidity and Mortality Weekly Report (MMWR)* from 2010 showed an annual incidence rate of 0/100,000 population. Reported rubella cases from 2007 to 2010 were 12, 16, 3, and 5, respectively. During this 4-year period only 2 cases of congenital rubella were reported. The annual incidence of rubella in the United States from 1980 to 2010 is illustrated in Figure 173-3.[90]

Another recent accomplishment has been rubella eradication from the Americas. Elimination of rubella

from the Americas was a remarkable achievement, especially because as many as 135,947 cases were confirmed in the Americas back in 1998.[70,88] In 2003, the Pan American Health Organization strengthened efforts to eliminate rubella and congenital rubella syndrome from the Americas by 2010. They accomplished this goal with high immunization coverage with programs targeting over 450 million people, including mass vaccination of adolescents and adults, and increased surveillance for rubella and congenital rubella syndrome that was integrated into existing measles surveillance programs. As a result of these comprehensive efforts, the last endemic rubella case documented in the Americas was reported in Argentina in February of 2009.[70,88]

In countries in which effective universal childhood immunization had not been achieved, epidemics continue to occur. While the number of rubella cases on a global scale continues to decrease, rubella still remains a problem in many areas of the world. Based on data from 2009 collected by the WHO, 121,344 rubella cases from 167 countries were reported, which is an 82 percent decrease from the 670,894 cases reported in 2000.[545,622] From 2000 to 2009, the percentage of reported rubella cases decreased by nearly 100 percent in the Americas region (39,228 to 18), 98 percent in the European region (621,039 to 11,623), and 35 percent in the Eastern Mediterranean region (3122 to 2030).[458] In contrast, reported rubella cases increased in the Western Pacific, Southeast Asian, and African regions during this period. There was a 12-fold increase (5475 to 73,077 cases) in the Western Pacific region, a 14-fold increase (1165 to 17,208 cases) in the Southeast Asian region, and a 20-fold increase (865 to 17,388 cases) in the African region.[458]

Epidemic rubella was documented in the former Czechoslovakia in 1972; in Australia in 1969 to 1970, 1975 to 1976, 1993 to 1996, and 2003; in Israel in 1972, 1979, and 1983; in Japan in 1975 to 1977 and 1982 to 1998; in Brazil in 1981 and 1997 to 2001; in Argentina in 2008; in the United Kingdom in 1971 to 1973, 1978, and 1983; and recently in some European countries.* A notable outbreak occurred in the Netherlands from 2004 to 2005, which primarily affected individuals unvaccinated secondary to religious beliefs. Three hundred eighty-seven cases of rubella were reported in the Netherlands and then spread to Canada, where an additional 309 cases were noted. An unfortunate consequence of vaccine refusal in these populations included 14 reported infants with congenital rubella infection and 2 fetal deaths.[238] Other recently reported outbreaks were also noted in Georgia in 2004 to 2005; northeastern Italy in 2008; Austria in 2008 to 2009; and Bosnia and Herzegovina in 2009, which were thought to be the result of vaccination failure rates during the war period in the early 1990s.†

The incidence of rubella varies with the epidemic cycle, the number of susceptible people within a population group, and the intrapersonal contact within the group. In closed populations such as military training centers and institutions for the mentally handicapped, the attack rate after the disease is introduced approaches 100 percent in susceptible individuals.[282,283,336] Introduction of disease in the family also affects virtually all susceptible persons.[204,205] In community epidemics, attack rates in susceptible people are estimated to range from 50 to 90 percent.

Age Groups

The age distribution of reported rubella cases and estimated incidence rates in Illinois, Massachusetts, and New York City for 1966 through 1968 and the entire United States for 1985 through 1987[79] are presented in Table 173-1. In the period immediately before the vaccine was introduced (1966 to 1968), the attack rate was highest in the 5- to 9-year-old age group, and the incidence was high in preschool-aged children. The overall reduction in the rate of rubella from the prevaccine era to 1987 was 99.2 percent. However, 50.2 percent of the cases reported in the period 1985 through 1988 were in persons older than 19 years; in the prevaccine period (1966 through 1968), the percentage in this age group was 10.2. In 1999, 75 percent of the reported cases occurred in persons older than 19 years.[456] During the period 1980 to 2002, outbreaks of rubella have occurred in prisons,[78] in colleges and universities,[76] in hospitals,[75,444,542] at work sites,[77,219,456] in communities with high foreign-born populations,[456] and among the Amish in six areas of the United States.[83]

From Communicable Disease Center. Rubella Surveillance-1964. *Morb Mortal Wkly Rep* 1964;13:349–60.

Because rubella was not a reportable disease in the United States until 1966, few age-specific incidence or prevalence data relating to epidemic disease are available. In Table 173-2, age-specific attack rates are presented for two communities during epidemic rubella in 1964.[401] The attack rate curves during epidemic rubella in 1964 are similar to the curve for the prevaccine nonepidemic period from 1966 to 1968 seen in Table 173-1. The overall attack rate during the 1964 epidemic in the two communities was 23 percent. Eighty-six percent of the cases occurred in children younger than 15 years of age. In 1999, 272 cases of rubella were reported in the United States, and of the 269 with known ages, only 14 percent occurred in children younger than 15 years.[456]

Antibody prevalence by age group in the prevaccine era in the St. Louis, Missouri area is presented in Figure 173-4.[101] As can be seen, rubella HI antibody prevalence went from less than 10 percent in children younger than 3 years of age to almost 80 percent in preadolescents. Surveys of adolescents and young women of child-bearing age conducted before 1969 generally have indicated an immunity rate (HI antibody titer ≥1:8) of approximately 75 to 85 percent.[402]

Immunity to rubella as indicated by the curve in Figure 173-4 obviously is affected by epidemic periods. With epidemic disease, the curve itself most probably maintains the same slope, but it moves to the left; prevalence of antibody in each age group of children increases significantly (perhaps 10% to 30%). However, studies in the prevaccine era on sera from young adults indicate that the percentage of susceptible persons in this age group is affected only slightly by epidemic disease.[182,402,510,513,617] In a survey of sera from 600 pregnant women in 1962, Sever and associates[510] noted that 17.5 percent had no detectable antibody. In a similar study in 1966 in which the mean age was slightly less (23.6 vs. 25.6 years), the percentage without detectable antibody was 7.8. Other surveys of rubella antibody in the sera of young adults acquired after the 1964 pandemic indicate a susceptibility rate in the 15- to 20-percent range, similar to pre-1964 data.[402,506,510]

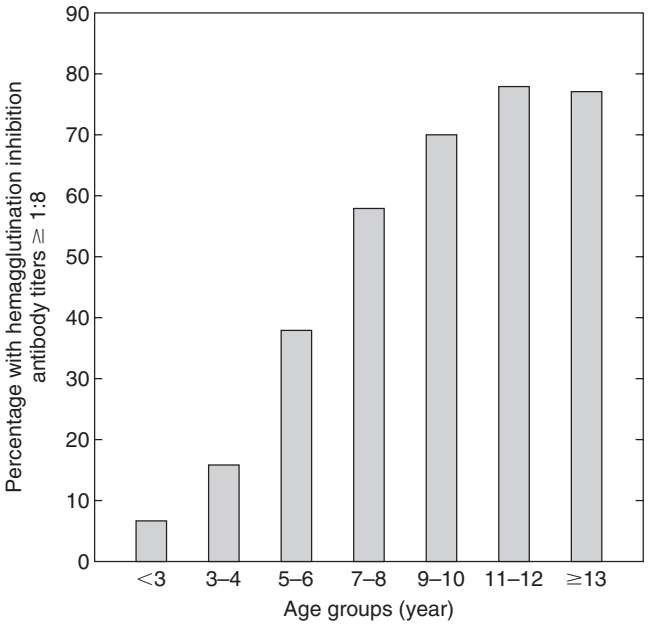

FIGURE 173-4 ■ **Percentage of children with rubella hemagglutination inhibition antibody titers of 1:8 or greater in a St. Louis, Missouri study in 1969.** (From Cherry JD. Copyright 1974 by the Alexander Graham Bell Association for the Deaf, 3417 Volta Place, NW, Washington, DC 20007.)

Effect of Vaccination

Rubella vaccine was licensed for use in the United States and many other countries in 1969, and it has been used extensively for more than 40 years.* However, before the 1990s, rubella-containing vaccines (RCV) were primarily limited to developed countries.[458] Significant progress has been made in increasing the number of countries that vaccinate routinely against rubella since 1996. As of 2009, the WHO estimates that 130/193 Member States use rubella vaccines in their national immunization schedules.[623] As a result of successful rubella vaccination efforts, endemic rubella elimination has been achieved in the United States since 2001 and in many other developed countries. In addition, the success of elimination of rubella from the region of the Americas, with the last reported case in 2009, provides hope that rubella could

*References 84, 115, 446, 457, 508, 516, 601.

be eradicated globally. However at the present, the risk for importation of rubella into the United State remains high because rubella continues to be endemic in many parts of the world.[40] Thus, it has been imperative to maintain rubella vaccination coverage greater than 90 percent in the United States, and recent data have supported achievement of these continued efforts. It has been estimated from the National Immunization Survey (NIS) in the United States that vaccination coverage for children 19 to 35 months of age was greater than 90 percent during 2005 to 2007 and data from school surveys estimate coverage for kindergarten and/or first-grade children to be greater than 95 percent.[457]

It has been estimated by mathematical models that when vaccine coverage is low through suboptimal childhood-only immunization efforts, viral circulation may be decreased such that children normally infected during childhood may remain susceptible until adolescence and adulthood. Thus, the paradoxical effect of sustained low levels of rubella immunization in childhood can actually increase the risk for congenital rubella syndrome more than without vaccine introduction. Thus, the WHO recommends rubella immunization coverage of 80 percent or greater, with at least one dose of rubella vaccine, because the effectiveness of one dose of vaccine is 95 percent or greater.[623]

The immunization effort in the United States initially focused on children.[142,315,317] A secondary goal was to immunize seronegative postpubertal girls and women of child-bearing age, but little effort was extended in this area until 1978. The overall effect of the immunization effort in the United States on the young adult population is difficult to interpret. As noted in Table 173-1 and subsequent data, the reported number of cases and the incidence of rubella decreased significantly from the prevaccine period until the present.[85,87,456,600] A marked reduction in the number of reported cases of congenital rubella also has occurred since 1969 (see Fig. 173-2). However, the actual number of cases and the incidence of rubella in adolescents and young adults did not decrease until 1981, and 58.2 percent of all patients in the period 1985 through 1987 were 15 years of age (see Table 173-1). Also alarming was the marked upswing in the number of congenital rubella cases in 1990 and 1991.[75,456] Antibody survey data reported between 1981 and 1993 indicate that 5 to 25 percent of the adolescent and young adult populations in the United States were susceptible to rubella.*

In four studies in which prevalence of rubella antibody was analyzed by the vaccination status of the participants, differences were significant.[328,377,412,465] Between 87 and 96 percent of vaccinated persons had rubella antibody, whereas only 70 to 80 percent of nonvaccinated persons had antibody.

U.S. serosurvey data for the period 1988 to 1994 found the following seropositive rates by age group: 6 to 11 years, 91.8 percent; 12 to 19 years, 82.6 percent; 20 to 29 years, 84.6 percent; 30 to 39 years, 88.7 percent; 40 to 49 years, 92.5 percent; 50 to 59 years, 93.7 percent; and 60 years and older, 95.7 percent.[160] In this survey, persons born from 1970 to 1974 were found to have the lowest rate of seropositivity (78%). For the period 1999 to 2004, the overall U.S. seropositivity level was 91.3 percent. Selected age-related rates in children aged 6 to 11 years and adolescents aged 12 to 19 years were 96.2 percent and 93.7 percent, respectively.[288] Seropositivity was 91.5 percent among women and 88.0 percent among men.

In contrast to the immunization program in the United States, which focused on children and elimination of epidemic rubella, immunization efforts in the United Kingdom and many other countries initially were aimed at girls aged 11 to 14 years, with selective immunization of women of child-bearing age. This approach would not be expected to disrupt the epidemic pattern of rubella but only to decrease disease in young adult women. Serologic surveys in the United Kingdom indicated a significant reduction in the number of seronegative persons in the target population.[109,242,377-379,450,470,565] In one study in which 10,000 serum samples were analyzed, 93 to 96 percent of females born after 1956 (who would have been offered rubella vaccine in school) were found to have antibody, whereas only 80 to 89 percent of those born before 1954 were found to have antibody.[109] In spite of the high level of antibody prevalence in women of child-bearing age, rubella infection in pregnancy and congenital rubella continued to be a major problem in the United Kingdom.[378,565] From 1971 to 1982, 625 cases of congenital rubella were reported, and from 1974 to 1981, 3273 women had their pregnancies terminated because they were infected with rubella or had been in contact with a person with rubella in England and Wales.[565]

In Finland, where initial immunization in 1975 involved 11- to 13-year-old girls and after 1982 involved a two-dose program for all children, the susceptibility rate in 1992 for 16- to 19-year-old girls was 3 to 5 percent, whereas for boys it was 30 percent.[577]

In Sweden, the initial immunization program, which began in 1973, targeted school girls, susceptible women after pregnancy, and women at special risk; their second program, which began in 1982, was a universal two-dose schedule at 18 months and 12 years.[53] The rate of susceptibility in pregnant women in Sweden decreased from 12 percent in 1975 to below 2 percent in 1994.

Recent serosurveys from around the world have noted varied rates of seropositivity in adults.[112,139,151,294,571] In Jordan, 90.9 percent of women of child-bearing age were immune, but only 83 percent of younger women aged 15 to 19 years were immune.[294] In Catalonia, Spain, 98.1 percent of adults had antibody to rubella[151]; in Israel, approximately 95 percent of women of child-bearing age were immune to rubella, whereas only approximately 85 percent of men of similar age were immune.[112] In this serosurvey, as many as 40 percent of adolescent men were rubella nonimmune, but only approximately 5 percent of similarly aged women were nonimmune. In Taiwan, the prevalence of rubella antibody in women varied markedly by birth cohort.[571] Rubella antibody was undetectable in 19.9 to 29.2 percent, 7.1 to 7.3 percent, and 8.3 to 10.4 percent of cohorts born before 1971, between 1971 and 1976, and after 1976,

*References 135, 153, 192, 304, 328, 412, 413, 465, 503, 538, 543, 592.

respectively.[342] In Argentina, in 2002, 91.2 percent of women of child-bearing age had antibody to rubella.[139] A survey of 17 European countries and Australia from 1996 to 2003 showed seronegativity among women of children-bearing age without protective immunity to rubella ranging from 1.4 to 13.4 percent, lowest among the Czech Republic and highest in Belgium.[399] Data from pregnant women in Canada from 2002 to 2005 found that 8.8 percent of tested women were seronegative for rubella and younger women were more likely to be seronegative.[302] A study from 2000 looking at women of child-bearing age in Morocco found that 16.6 percent were seronegative for rubella immunoglobulin (Ig)G antibodies.[66] Seroprevalence data from Nepal in 2008 demonstrated that 90.8 percent of women of child-bearing age were seropositive for rubella.[579]

Congenital Rubella

Rubella infection during pregnancy, especially during the first 12 weeks of gestation, can lead to miscarriage, intrauterine fetal death, and a variety of birth defects associated with congenital rubella syndrome.[158,517] As a result of rubella vaccine implementation, the number of cases of congenital rubella has decreased dramatically, especially in developed countries. However, in many regions of the world, immunization against rubella is not standard practice, and congenital rubella infection and its devastating consequences remain an ongoing problem. In many developing countries that have still not implemented mass rubella immunization campaigns, congenital rubella syndrome annual rates are actually similar to those over 15 years ago in 1996. Congenital rubella syndrome at that time was estimated at 110,000 cases annually (range, 14,000 to 308,000 cases), with an estimated 22,000 cases in Africa; 46,000 cases in Southeast Asia; and 12,634 cases in the western Pacific regions.[545,623] Unfortunately, accurate data have been severely limited by underreporting. Thus, in 2009, only 165 cases of congenital rubella syndrome were reported and 67 of these were localized to the eastern Mediterranean region.[545] Seroprevalence data and models also attest to the issue of underreporting. These models have predicted approximately 46,621 infants annually with congenital rubella syndrome in the Southeast Asian region alone, although recently only approximately 13 cases were reported annually in this region.[622]

Congenital rubella was not a reportable disease in the United States until 1966, so good data on incidence and prevalence during epidemics of rubella are not available. In the 1964 to 1965 rubella epidemic in the United States, 20,000 cases of congenital rubella occurred, 5000 therapeutic abortions were performed, fetal wastage in excess of 6250 was reported, and more than 2100 neonatal deaths occurred.[402] Estimates of the risk for acquiring congenital rubella after maternal infection vary considerably across studies. In general, studies performed before 1964, which included nonepidemic periods, tended to underestimate the risk, whereas early retrospective studies after epidemics resulted in high incidence values.[183] Clearly, however, the individual risk for acquiring congenital rubella depends on the month of pregnancy in which maternal infection occurs. Sallomi[480] analyzed eight published studies that met his rigid criteria and noted the following rates of anomalies by gestational age when maternal infection occurred: weeks 1 to 4, 61 percent; weeks 5 to 8, 26 percent; and weeks 9 to 12, 8 percent. In pregnancies complicated by rubella in weeks 1 to 8, only 36 percent ended in normal live births, 39 percent ended in abortion or stillbirth, and 25 percent produced gross fetal anomalies. Peckham[426] noted that 85 percent of infants born to mothers infected during the first 8 weeks of pregnancy had detectable defects during the first 4 years of life. Infection at other times during pregnancy revealed the following rates of detectable defects: 9 to 12 weeks, 52 percent; 13 to 20 weeks, 16 percent; and after 20 weeks, no defect. Other studies indicate a risk for malformation of 3 percent and a risk for abortion and stillbirth of 4 percent when intervals from conception to acquisition of rubella are greater than 12 weeks.[111]

Infection with rubella virus confers lifelong immunity against clinical illness, but asymptomatic reinfection does occur. Asymptomatic reinfection is noted frequently in pregnant women, but it generally has not been considered a risk to the fetus. However, in rare instances, reinfection has resulted in severely damaged babies.*

Transmission

Rubella infection generally is thought to be spread by the respiratory route. Although definitive evidence supporting this assumption is not available, data from volunteer projects and studies of natural disease strongly support this view.[227,263,493] Infected persons regularly shed large concentrations of virus in the nose and throat, and droplets of secretions are released into the environment, which allows respiratory-to-respiratory transmission. Also possible is that the initial hosts may contaminate their own hands and then transmit the infectious agent to environmental surfaces or directly to contacts. In this circumstance, new hosts can acquire infection through the fomite-hand-respiratory or hand-hand-respiratory route.

In experimental transmission studies, Green and colleagues[227] noted that efficient transmission of infection to susceptible persons required prolonged, repeated contact; after a brief, single contact, only 1/5 children acquired disease, whereas all but 1/17 patients with prolonged, repeated contact were infected. Although the period of communicability has never been determined accurately, almost 100 years ago the period of infectivity was noted to precede the eruptive phase of illness.[229] Volunteer studies indicate that virus is present in nasopharyngeal secretions from 7 days before to 14 days after the onset of rash.[227,263] Maximal shedding and presumably maximal transmissibility occur for an 11-day period of 5 days before to 6 days after the appearance of rash. Infants with congenital rubella shed virus from the nose and throat for many months and have been responsible for the spread of virus to susceptible contacts.[281,491]

Seasonal Patterns

Rubella is a disease of winter and spring, with the largest number of cases in the United States occurring in March, April, and May.[401,402] This seasonal pattern occurs in years with both a high and a low incidence of rubella. Presumably, some transmission and sporadic illness occur throughout the year in large urban areas.

Geographic Distribution

Rubella has been recognized in many countries throughout the world. In recent years, more information about circulating wild-type rubella viruses has been uncovered largely because of global virologic surveillance efforts for measles, which incorporates surveillance for rubella as well. The WHO Global Measles and Rubella Network (LabNet), which was developed in 2000, serves over 183 countries and includes over 690 laboratories, which helps confirm suspected cases of rubella and monitors rubella transmission patterns.[172,473] Nine of the 13 viral genotypes were identified during surveillance efforts from 2005 to 2010. Viruses 1E, 1G, and 2B have the widest geographic distribution and are the most frequently identified. 1E rubella viruses were found in the Middle East, Europe, Southeast Asia, Africa, and Western Pacific countries. This genotype is also the dominant one found in China. 1G genotype viruses were found in Europe and Africa. The 2B genotype viruses were found in the Middle East, Europe, Southeast Asia, and South and Central America, Africa, and Western Pacific countries.[2] In remote islands, rubella may not be endemic, so large segments of the population may be susceptible.[57,267] In these locales, the introduction of rubella results in epidemic infection that involves approximately 90 percent of the susceptible population. In populated areas of the world in the prevaccine era, rubella was both endemic and epidemic, and between 80 and 90 percent of the adult population had serum rubella antibody.[111] An interesting note is that in the prevaccine era in several well-populated large islands that were not remote (Jamaica, Taiwan, Barbados, Trinidad, Hawaii, and Japan), a smaller percentage of the total population had antibody and rubella was not endemic.[111,169,205,224]

Other Factors

Sex

The incidence of clinical rubella is similar in boys and girls.[401,402] In adults, more cases of rubella are reported in women.[402] This finding possibly is the result of interest and concern related to congenital rubella rather than a true difference on the basis of sex. Of interest is that in rubella vaccine trials, girls have been noted to have geometric mean convalescent-phase antibody titers higher than those of boys.[375,530]

Mitchell and associates[383] studied the IgG, IgM, and IgA antibody responses in men and women to rubella virus structural proteins (E1, E2, and C). IgA E2 antibodies did not develop in men, but they did in women. Men had lower IgG antibody to E2, an earlier onset of E1-specific IgG and IgM antibodies, and a greater proportion of total antibody against E1 than women did. In another study, Mitchell[382] reported that men had a more rapid cell-mediated immune response to whole, inactivated rubella virus and a panel of rubella virus peptides after reimmunization than women did.

Genetics

Hattis and associates[259] showed that individuals differ in their ability to transmit rubella. During a rubella epidemic, they noted a small number of persons who had high potential for transmitting virus to susceptible persons ("spreaders"). Most persons demonstrated only minimal virus transmission ("nonspreaders"). Honeyman and colleagues[273,275] suggest that the ability to spread rubella virus is favored by the cell surface antigen HLA or the combination of HLA and HLA. In a rubella vaccine trial, Spencer and associates[530] noted that 44 percent of persons with high rubella HI antibody titer (≥1:512) responses had HLA. In this study, a high convalescent-phase geometric mean antibody titer also was noted to occur in subjects with the AB blood type.

Ovsyannikova and associates[417] recently studied HLA haplotypes in the genetic control of immune response to measles-mumps-rubella (MMR) vaccine. They found that DRB1*04-DQB1*03-DPB1*03 was associated with high lymphoproliferative responses to rubella vaccine virus. They found that specific class II HLA haplotypes (DRB1*04-DQB1*03-DPB1*03 and DRB1*13/14-DQB1*06-DPB1*03) were associated with higher lymphoproliferative responses to rubella virus vaccine and the haplotype DRB1*07-DQB1*02-DPB1*11 was associated with lower lymphoproliferative responses.[418] Kennedy and associates[305] found that homozygosity within HLA DPB1 locus is associated with increased levels of rubella-specific IgG. Haralambieva and colleagues[250] found associations between polymorphisms within the 2′-5′-oligoadenylate synthetase *(OAS)* gene cluster and rubella virus–specific cytokine secretion (IL-2, IL-10, and IL-6) and antibody levels.

PATHOLOGY AND PATHOGENESIS

Viral Infection

The sequence of events in uncomplicated, postnatally acquired rubella is presented in Table 173-3. Although much is known about rubella infection in humans, considerable gaps regarding specific events exist.[227,261-263,493] Estimates for the timing of events in rubella infection (see Table 173-3) have come from volunteer inoculation studies. In many instances, artificial inoculation has resulted in a reduction in the length of the incubation period of clinical disease. This finding suggests that the size of inoculum is important in the initial generation of human infection. It also helps explain the rather wide boundaries of the incubation period noted in many clinical studies.[229,372,486]

The primary site of infection is the respiratory epithelium of the nasopharynx. Initial infection of the

3-8	First evidence of nasopharyngeal viral shedding
6-20	Viremia (virus free in serum and associated with leukocytes)
8-14	Establishment of infection in the skin and other viremic sites, including generalized nasopharyngeal involvement
10-17	Maximal viremia and viruria
10-24	Maximal nasopharyngeal viral shedding
17-19	Viremia decreases and then ceases. Viral content at viremic sites rapidly diminishes

From references 227, 261-263, 493.

respiratory epithelium apparently is minor; a more important event is early spread of virus to the regional lymphatics. In volunteers given 100 $TCID_{50}$ of rubella virus intranasally, viral multiplication at the respiratory site was noted on the third day.[493] After viremia develops, extensive nasopharyngeal infection occurs. In persons who have received either attenuated or unattenuated virus by the subcutaneous route, nasopharyngeal shedding in varying concentrations always occurs.[102,104,227,493] Concentrations of virus generally are greater in specimens collected from the nose than in those from the throat.

Viremia peaks just before the onset of exanthem and disappears shortly thereafter. In contrast, virus continues to be present consistently in the nasopharynx for a 6-day period after the onset of rash and occasionally for an additional week thereafter.[227] In addition to the blood and nasopharynx, other sites from which rubella virus has been recovered are the lymph nodes,[201] urine,[493] cerebrospinal fluid,[534] conjunctival sac,[262] breast milk,[62] synovial fluid,[266] and lungs.[518] In patients with rubella, the virus was recovered from the skin at sites both with rash and without rash.[261,262]

Immunologic Events

Antibody

After having natural or vaccine rubella viral infection, patients regularly have an antibody response. Serum antibodies to different rubella viral antigens can be measured by HI, CF, neutralization, immunofluorescence, precipitation, radioimmunoassay, ELISA, single radial hemolysis, passive hemagglutination, latex agglutination, and platelet aggregation.*

In natural postnatal rubella infection, HI and neutralizing antibodies appear 14 to 18 days after exposure, at the time of the rash. HI antibody titers usually peak approximately 2 weeks after the onset of clinical illness, stay at a high level for several weeks, decrease about fourfold during the course of a year's time, and then generally persist for life. Immunofluorescence, ELISA, radioimmunoassay, and latex agglutination reveal antibody patterns similar to those determined by HI.[265] Antibody detected by passive hemagglutination does not appear until 3 to 4 weeks after the onset of illness, and that detected by single radial hemolysis is delayed until 1 to 2 weeks after onset. In an Amazon Indian tribe, the geometric mean rubella HI antibody titer 12 years after infection, with no intercurrent rubella exposure, was 1:33.[44] The pattern of the neutralizing antibody response is similar to the HI antibody response, except that the peak is delayed slightly. Brody and colleagues[57] noted that all but 10 percent of an island population had rubella neutralizing antibody 22 years after the time of epidemic illness.

CF antibody first appears approximately a week after HI and neutralizing antibody, peaks approximately 1 month after illness, and in general does not persist as long as does either HI or neutralizing antibody. On occasion, the CF antibody response is delayed and appears 1 month after the exanthem, with peak titers occurring 2 to 5 months later. Sever and colleagues[516] noted CF antibodies in only 44 percent of persons with neutralizing antibody who were studied 10 to 20 years after illness. The use of an antigen prepared by alkaline extraction has increased the sensitivity of CF, but low levels of antibody still are best identified by HI, ELISA, or neutralization.[436,498]

After natural infection occurs, precipitating antibodies develop to both theta and iota antigen.[330] Antibody to theta antigen appears early, parallels HI antibody, and is persistent. In contrast, the response to iota antigen is delayed, with a slow rise in concentration during a 2- to 3-month period. Five years after infection has occurred, anti-iota antibody cannot be detected.

After immunization has been administered, the antibody response pattern varies according to the type of vaccine used.* With RA 27/3 vaccine, the serum antibody response is similar to that after natural disease, except that the peak HI and neutralizing antibody titers attained usually are lower. Serum antibody responses noted after HPV-77 and Cendehill vaccine viral infection are different from those found after natural infection in that CF

*References 17, 43, 124, 148, 175, 212, 222, 243, 265, 271, 332, 338, 355, 369-371, 396, 427, 436, 514, 515, 565, 585, 588, 614, 629.

*References 45, 330, 411, 439, 440, 490, 595.

and anti-iota antibodies are noted only irregularly and then in minimal concentration.

Primary rubella virus infection, either naturally acquired or vaccine induced, is characterized by the initial appearance of antibody in the IgM and IgG serum components.* In general, the IgM-specific response is short-lived and not detectable more than 8 weeks after the onset of infection. On occasion, it has been detected in the serum for extended periods.

IgA nasal HI, ELISA, and neutralizing antibodies also occur regularly after natural viral infection. After immunization, the nasal antibody response varies with the type of vaccine and the route of administration.† After subcutaneous immunization with human papillomavirus (HPV)-77 vaccine is given, rubella-specific nasal IgA antibody is a rare finding; it occurs in most subjects who receive RA 27/3 vaccine administered intranasally and in approximately half of those given this vaccine by the subcutaneous route.

Specific Cell-Mediated Responses

Rubella-specific, cell-mediated lymphocyte responses regularly occur after infection with rubella virus.‡

Steele and associates,[537] using an in vitro lymphocyte-mediated cytotoxicity assay, first noted that lymphocytes from persons who previously had rubella caused cell destruction in a tissue culture chronically infected with rubella virus. Rubella antigen–specific, cell-mediated immunity also has been demonstrated in lymphocyte cultures by blast transformation, production of migration-inhibition factor, and production of interferon (IFN).§ With vaccination, rubella-specific, cell-mediated immunity first was noted to occur 7 days after immunization, with peak responses at 3 weeks.[587,589] Honeyman and associates[276] noted that the rubella antigen–specific, cell-mediated response commenced 1 week before the humoral immune response occurred in both natural and vaccine-induced rubella viral infection. They also noted that the cell-mediated response was of greater magnitude and duration after natural disease than after immunization. Rossier and associates[472] studied cloistered nuns and noted that specific cell-mediated immunity to rubella virus persisted until they reached 79 years of age in the probable absence of reinfection.

Morag and colleagues[392] demonstrated the specific appearance of cell-mediated immunity in tonsillar lymphoid tissue after natural infection or intranasal immunization with rubella vaccine. This responsiveness was conspicuously low after vaccination was administered by the subcutaneous route. In most instances, the presence of cell-mediated responsiveness correlates with the presence of antibody; specific rubella lymphocyte transformation has been noted in the absence of antibody, however.[527] The magnitude of the rubella-specific, cell-mediated response is suppressed during pregnancy.[559]

McCarthy and colleagues[359] identified potential determinants of human cellular immunity to rubella virus by using synthetic peptides representing well-defined sequences of rubella virus structural proteins. They used the following peptide subsequences: two capsid domains (C_1 to C_{29} and C_{64} to C_{97}), a glycoprotein E1 domain ($E1_{202}$ to $E1_{283}$), and a glycoprotein E2 domain ($E2_{31}$ to $E2_{105}$). All but the C_{64} to C_{97} subsequences stimulated specific lymphoproliferative responses in peripheral blood mononuclear cells in 25 to 50 percent of immune subjects. The immunodominant T-proliferative epitope (C_{14} to C_{29}) was recognized by only 50 percent of the peripheral blood mononuclear cells of the study population. Relatively immunodominant T-cell epitopes vary among different persons.

Using a lymphocyte proliferation assay, Mitchell and associates[385] reported positive cell-mediated immune responses to 16 peptides, including 6 that contained antibody neutralization domains after revaccination.

Nonspecific Responses

A large number of nonspecific, immunologically related responses can be demonstrated during rubella virus infections. Niwa and Kanoh[403] performed a comprehensive study of these responses in 85 children and adults during an epidemic of rubella. They noted a decreased number of total leukocytes, neutrophils, and T cells initially, which returned to normal values within 1 week. Some patients had slightly elevated levels of serum IgM, and total hemolytic complement was elevated in 12/30 patients. Marked increases in C4 and C9 also were present. In addition, they noted a marked insensitivity to dinitrochlorobenzene and purified protein derivatives in many patients. Atypical lymphocytes, autoantibodies, and reduced blastogenesis as measured by phytohemagglutinin (PHA) stimulation were noted in some patients. Other studies consistently have demonstrated a reduction in the lymphocyte response to PHA.* In general, this reduction lasts less than 1 month, and infections with attenuated strains of rubella vaccine virus are less immunosuppressive than are infections with unattenuated rubella virus.

Hyypiä and colleagues[290] noted that during rubella virus infection, the proportion of suppressor-cytotoxic T cells was increased and the proportion of helper-inducer T cells was decreased. Polyclonal activation of B cells was associated with these findings.[291]

Zaknun and coworkers[626] noted a marked increase in urine neopterin levels in two children with acute rubella. Their levels increased dramatically 4 days before the onset of exanthem.

Fetal Events

Viral Infection

A considerable amount of information about fetal infection became available from extensive studies during the

*References 32, 42, 128, 147, 236, 424, 425, 535.

1964 epidemic of rubella,* and further information has been obtained more recently from both natural and vaccine viral infections.† In spite of the number and extent of investigations performed to date, we know little about transmission of the virus to the fetus in maternal infections in the latter half of pregnancy.

With maternal infection during the first trimester, placental infection regularly occurs and often persists throughout the remainder of the pregnancy. In the therapeutic abortion studies of Alford and associates,[11] fetal infection occurred in approximately 50 percent of placental infections. However, other studies have revealed almost identical isolation rates from both placental and fetal tissue.[453,558] Persistent infection is the usual outcome of first-trimester fetal infection. This fetal infection usually involves multiple organs, and virus can be isolated at birth regularly from the throat, rectum, and urine.[281,434]

Little is known about events in second- and third-trimester maternal rubella infection. Most probably, placental infection is a regular occurrence, and transmission of virus to the infant in utero also may occur regularly. Because few infants have defects when they are born after maternal rubella infection in the second and third trimesters, a careful search for rubella infection in these infants by virologic or serologic methods rarely has been conducted. Random studies seem to indicate that rubella virus often infects the fetus after the first trimester and occasionally the infection becomes persistent.‡ Other studies have failed to show virologic or serologic evidence of infection in infants in whom maternal rubella occurred in the second and third trimesters.[103,390,541]

With maternal rubella infection, the cervix also is involved, so fetal infection could occur by the ascending route as well as by primary placental infection.[103,390,507,541,580] In addition, fetal infection has resulted from maternal disease that occurred before conception.[183,611,624]

Rubella virus can be recovered regularly after birth from infants with congenital rubella. The percentage of infants with persistent infection decreases during the course of the first year of life; by their first birthdays, between 10 and 20 percent of children still shed virus in nasopharyngeal secretions.[118,453] Rawls and colleagues[453] were unable to isolate virus from the throats of 15 congenitally infected infants after they reached 18 months of age, and Sever and Monif[509] and Cooper and Krugman[118] were unable to demonstrate persistence of nasopharyngeal virus in older children. A 4.5-year-old boy with congenital rubella was found on one occasion to be shedding rubella virus in the throat.[519]

Immunologic Findings

Specific Antibody. Humoral antibody in a congenitally infected fetus is acquired transplacentally from the mother and is produced actively by the fetus. In a normal maternal-fetal relationship, transport of antibody to the fetus is minimal until the midpoint of the second trimester (16 to 20 weeks).[10,11] With first-trimester maternal infection (transplacentally acquired), rubella antibody titers in serum amount to only approximately 5 percent of maternal values. The fetal immune system becomes functional during the second trimester,[329] and small amounts of specific rubella fetal IgM antibody can be detected. From the midpoint of pregnancy, antibody levels in the developing fetus rise so that at birth, the maternal and infant values are similar. Although the values of total antibody are similar, the composition is different. Maternal antibody at the time of delivery usually is composed entirely of IgG. In contrast, the infant titer consists of fetal IgM, presumably fetal IgG, and occasionally fetal IgA and transplacentally derived maternal IgG.

Long-term rubella antibody patterns in congenitally infected infants after birth are different from those of their mothers or from those of a group of children with acquired disease.[119,248,301,571] Cooper and colleagues[116] monitored a group of 223 mothers of children with congenital rubella and noted that at the end of 5 years, all still had detectable HI antibody and the geometric mean titer for the group had undergone a fourfold reduction. In contrast, 5-year follow-up of the congenitally infected infants revealed a 16-fold decline in geometric mean titer; 8/29 infants had serum HI antibody titers less than 1:8 when they were examined at 5 years of age. Other investigators observed similar declines in rubella antibody titers of congenitally infected infants.[251,307,573]

Another unique aspect of rubella antibody in congenitally infected infants is the persistence of specific IgM. Cradock-Watson and colleagues[127] studied 40 infants with congenital rubella and noted that IgM antibody persisted for approximately 6 months in most cases and for up to 2 years in a few children. de Mazancourt and colleagues[140] studied the antibody response to rubella virus structural proteins in infants with congenital rubella syndrome and found that the immunoprecipitation patterns were different from those in sera from postnatally infected adults. The sera from congenitally infected infants had little or no C-specific antibody, occasionally only antibody to E1 was precipitated, E1 protein was precipitated in relative excess of E2 protein, and the relative amount of E2 antibody was greater than antibody to E1.

Specific Cell-Mediated Immunity. Rubella-specific, cell-mediated immune responses have been studied in children with congenital rubella by the following assays: lymphocyte-mediated cytotoxicity, lymphocyte transformation, lymphocyte IFN production, and leukocyte migration-inhibition factor production.[63,200] By all methods of study, infants with congenital rubella have decreased rubella-specific, cell-mediated responses in contrast to persons who previously had acquired rubella postnatally. Buimovici-Klein and associates[63] noted that the degree of suppression correlated with the time of in utero infection: the earlier in pregnancy the maternal infection, the greater is the depression of specific cell-mediated responses. In the study of an infant with late-onset congenital rubella syndrome, Verder and associates[586] noted decreased activity of killer and natural

*References 11, 73, 103, 118, 120, 156, 248, 252-255, 281, 387-390, 434, 453, 491, 494, 541, 611.

killer cells and alloreactive direct cytotoxic cells. Their data indicated that defective cytotoxic effector cell function was the primary cause for failure to eliminate virus in the illness.

Nonspecific Responses. Desmyter and colleagues[145] noted that infants with congenital rubella produced normal amounts of IFN after receiving measles immunization. They also found that the clinical response and antibody development in these measles-vaccinated children were similar to those in normal children. Lebon and associates[334] noted that sera collected from rubella-infected fetuses and infants with congenital rubella contain an acid-labile IFN. Michaels[373] observed that infants with congenital rubella who still were shedding virus in their throat or urine had depressed antibody responses to diphtheria and tetanus toxoids. White and colleagues[609] reported decreased in vitro lymphocyte blast transformation responses to vaccinia and diphtheria toxoid antigens in children with congenital rubella in contrast to normal children. They also noted depressed skin reactivity to intradermal *Candida* antigen in the congenital rubella group. Buimovici-Klein and associates[63] observed a marked reduction in lymphocyte transformation after PHA stimulation in their congenital rubella group. The most marked defect was seen in children in whom maternal rubella occurred during the first 8 weeks of pregnancy. Pukhalsky and associates[447] noted that rubella immunization resulted in defective lymphocyte response to a mitogen (PHA). After immunization, serum IFN-α was slightly increased at day 7 and then fell significantly so that it was not measurable at day 30 in several subjects. The IFN-α/interleukin-10 ratio significantly decreased after immunization.

Pathology

Postnatally Acquired Disease

Almost no data on the histologic findings in uncomplicated rubella are available, but occasionally, postmortem tissue has been studied from patients with encephalitis. Giuliani and associates[216] studied lymph nodes from patients with rubella and noted edema, reticulum cell hyperplasia, and loss of the usual follicular morphologic features. Sherman and associates[518] reported six cases of rubella encephalitis and noted the autopsy findings in three cases. They specifically searched all organs for inclusion bodies, syncytial giant cells, focal cellular necrosis, and unusual proliferative changes, but none of these was found. Only mild, nonspecific, follicular hyperplasia in the spleen and lymph nodes was seen. Histologic examination of the brain of a 7-year-old girl who died of encephalitis revealed diffuse swelling, nonspecific degeneration, and a sparse, mononuclear perivascular and meningeal exudate.

A synovial biopsy specimen in a woman with rubella arthritis revealed scattered areas of fibrinopurulent exudate and synovial cell hyperplasia; inflammatory cell infiltration composed mainly of lymphocytic cells was present, and vascularity was increased.[625]

Congenital Infection

In contrast to postnatal rubella, the pathologic process of congenital infection has been studied extensively.*

Table 173-4 summarizes the main pathologic findings by anatomic location or system in congenital rubella. As noted, defects in congenital rubella result from both specific cell damage and cellular deficiency. Although specific cellular necrosis is important in certain early lesions such as in the inner ear, of greater overall importance are the secondary effects of generalized vascular damage. Also of presumed major importance is the noncytolytic cellular infection characteristic of rubella virus. It results in mitotic arrest and a reduction in the total number of cells in many organs.

CLINICAL MANIFESTATIONS

Postnatal Illness

Although clinical rubella is a distinctive exanthematous disease, its features are not as clearly discernible as are those of measles or chickenpox.† The exanthematous illnesses caused by enteroviruses, adenoviruses, and other common respiratory viruses often are clinically similar or identical to those of rubella (see Chapter 58). Because of these other viral illnesses that simulate rubella, descriptions of clinical rubella made before modern virologic diagnostic techniques became available are not always accurate, particularly when rubella in infants and young children is described because exanthems caused by other viruses occur most commonly in these age groups. Unfortunately, in spite of the availability of a vast amount of clinical material collected during the rubella epidemic of 1964, most clinical knowledge relating to postnatally acquired rubella was formulated before the present virologic era.

Incubation Period

Although prodromal complaints and lymphadenopathy frequently precede the development of exanthem in rubella, the incubation period in most studies has been calculated as being from the time of exposure to the onset of rash. Almost a century ago, Michael[373] reviewed the incubation periods in 59 different reports and noted a variation of 5 days to 4 weeks. However, in most reports, the minimal incubation time was 14 days or more and the maximum was 17 to 21 days. The mean incubation period from modern reviews is considered to be 18 ± 3 days.

In carefully controlled studies, Green and colleagues[227] noted an incubation time of 13 to 15 days to the onset of rash after the intramuscular inoculation of serum from

TABLE 173-4 **Pathologic Findings in Congenital Rubella**

Anatomic Location or System	Gross and Microscopic Findings	References
Placenta	Perivascular mononuclear cellular infiltration in the deciduas Edema, fibrosis, and necrosis of villi; cytoplasm inclusion bodies noted in swollen Hofbauer cells in villous stroma	414
Generalized growth retardation	Subnormal number of cells in many organs	397
Nervous system	Chronic meningitis with infiltrates of large mononuclear cells, lymphocytes, and plasma cells in the leptomeninges Vascular degeneration, ischemic lesions, and retardation of myelinization throughout brain	467, 468, 523, 560
Eye	Lens: Cataract, cortical liquefaction, and spherophakia Iris and ciliary body: Necrosis of ciliary body, iridocyclitis, iris atrophy, and pigmentation defects Retina: Posterior pigmentary disturbances Cornea: Usually normal; occasional endothelial degeneration Optic nerve: Posterior bowing	49
Ear	Hemorrhage in fetal cochlea resulting in epithelial necrosis Inflammatory cells in stria vascularis Adhesions between Reissner's membrane and tectorial membrane Sacculocochlear degeneration of Scheibe (strial atrophy, collapse of Reissner's membrane, atrophy of organ of Corti, rolled-up tectorial membranes, and collapse and degeneration of sacculus) noted after birth	196, 197, 598
Cardiovascular	Common heart defects in order of frequency: Patent ductus arteriosus, pulmonary artery stenosis, ventricular septal defect, and atrial septal defect (These rubella-induced lesions do not differ from similar non–rubella-induced lesions.) Myocarditis with swelling of muscle fibers and loss of striations; necrosis Intimal proliferation of major arteries	6, 165, 189, 313, 316, 415, 601
Pulmonary	Chronic interstitial pneumonia with large mononuclear cells, lymphocytes, and plasma cells within interstitial spaces and alveoli	313, 432, 523
Liver	Hyalinization and swelling of hepatocytes, hematopoiesis, and multinucleated giant cells	167, 168, 539, 544
Skin	Purpuric lesion: Focal areas of erythropoiesis in dermis and upper subcutaneous adipose tissue Chronic reticulated rash: Acute and chronic inflammatory cells and histiocytes in dermis Edema in dermal papillae	72, 310
Bone	Thinning of metaphyseal trabeculae and decrease in number of osteoblasts and osteoclasts Many plasma cells in metaphyses and cartilaginous epiphyses and around vessels Occasional giant cells with cytoplasmic inclusions Thinning of cartilage	454, 475, 506, 608
Muscle	Focal abnormalities: Very small fibers with darkly staining nuclei and muscle bundles containing empty connective tissue tubes	530
Teeth	Necrosis of enamel-forming epithelial cells	232, 567
Hematologic	Transient thrombocytopenia with decreased megakaryocytes in bone marrow; increased platelet adhesiveness and platelet agglutinins Lymph node consistent with histiocytosis; unorganized cell mass made up of mononuclear cells with dense round nuclei and irregularly shaped cytoplasm	33, 108, 442, 452
Immunologic	Spleen: Fibrosis Loss of normal architecture and absence of germinal centers in spleen and lymph nodes Dysgammaglobulinemia usually with decreased IgG and IgA and elevated IgM	108, 245, 441, 462

rubella-infected patients and a longer incubation time (16 to 21 days) in cases acquired by contact with ill patients. In similar volunteer studies in young adults, Schiff and colleagues[493] noted that the onset of rash occurred 11 to 12 days after the administration of 100 $TCID_{50}$ of tissue culture–grown rubella virus. The investigators attributed this shorter incubation period to a larger inoculum than that occurring in natural transmission.

Prodromal Period

Symptoms reported before the onset of rash in rubella vary with age. In young children, the first evidence of disease usually is the appearance of rash. On occasion, mild coryza and diarrhea precede the development of exanthem in younger patients. In contrast to the lack of prodrome in children, adolescents and adults usually have

symptoms before the onset of rash (Cherry JS, unpublished data, 1963-1973).[180,231] In one study, 94 percent of college students with rubella had prodromal symptoms. In decreasing order of frequency, the reported symptoms were eye pain, sore throat, headache, swollen glands, fever, aches, chills, anorexia, and nausea.[180] Gross and associates[231] reported prodromal upper respiratory tract complaints, including malaise, cough, sore throat, red eyes, and runny nose, in 65 percent of an infected adolescent study group.

Prodromal symptoms usually precede the onset of rash by 1 to 5 days. In the studies of Green and associates[227] involving volunteers, the onset of lymphadenopathy commonly was noted 5 to 7 days before the onset of rash. In contrast, Schiff and colleagues[493] observed the appearance of lymphadenopathy only 1 day before the rash appeared; fever was noted 1 to 4 days before the onset of rash, and most of the volunteers also had malaise and sore throat. Pain on lateral and upward eye movement occurs frequently and occasionally is distressing (Cherry JD, unpublished data, 1963-1976).[180]

Exanthem Period

The rubella exanthem appears first on the face. Spread of the rash is centrifugal from the head toward the hands and feet. The progression, extent, and duration of the exanthem vary considerably. In a typical case, the rash involves the entire body during the first 24 hours, begins to fade on the face during the second day, and has disappeared from the body by the end of the third day. The characteristic rash is erythematous, maculopapular, and discrete (Fig. 173-5). Its appearance on an adolescent's face occasionally is confused initially with an exacerbation of acne. Frequently, the rash is only macular with a scarlatiniform appearance. In some patients, the rash is present for less than a day, although sometimes it persists for 5 days or longer. Particularly in adults, the exanthem frequently is pruritic. This complaint is troublesome because it often leads the patient as well as the physician to attribute the rash to an allergic cause rather than rubella virus infection.

FIGURE 173-5 ■ Rubella exanthem. The rash is erythematous, maculopapular, and discrete. (From Cherry JD. Newer viral exanthems. *Adv Pediatr* 1969;16:233–86.)

The exanthem occasionally progresses to confluence with a morbilliform appearance. In these cases, the rash usually is less coppery and pinker than that in measles and heals without desquamation or brownish discoloration. The typical picture of erythema infectiosum (slapped-cheek appearance and reticular rash) has been observed in rubella-infected patients. Balfour and associates[24] described eight children with erythema infectiosum from whom rubella virus was recovered concurrently and two additional children with serologic evidence of rubella infection. The preliminary results of volunteer studies with a virus recovered from one of the patients in this study produced a slapped-cheek appearance but a nonreticulated rash in four of five men. One 3-year-old child from whom the author recovered rubella virus had typical erythema infectiosum (Cherry JD, unpublished data, 1972). A 14-month-old girl had a roseola-like illness and arthritis.[266]

In the volunteer studies of Schiff and associates,[493] the rash was noted to be pink-red and maculopapular. It appeared initially on the face, chest, upper part of the arms, and shoulders and then spread rapidly over the abdomen, back, and thighs. It developed into an erythematous blush on the face and abdomen. The median duration was 3 days, with extremes of 2 and 5 days. No pruritus was noted.

Rubella infection without rash is a rather common occurrence. In some patients, the infection is without symptoms; in other persons, careful questioning reveals prodromal symptoms, and lymphadenopathy is found on examination. Green and associates[227] noted that approximately 25 percent of exposed children who became infected had subclinical infection. In an intensive study of 46 susceptible children and adults, all but one subject had clinical symptoms with infection[512]; 60 percent of the group had both rash and characteristic posterior auricular or suboccipital lymphadenopathy, and 40 percent had lymphadenopathy without rash. In another study of rubella in an institution for intellectually challenged children, Horstmann and associates[284] noted that only approximately half of the children who became infected had a rash. Of nine children without rash, significant posterior auricular lymph node enlargement developed in five. Buescher[59] reported a subclinical-to-clinical infection ratio in a military recruit population of 6.5 : 1.

Lymphadenopathy is a major clinical manifestation of rubella. The most characteristic enlargement occurs in the suboccipital and posterior auricular nodes, but generalized involvement occurs as well. In the volunteer studies of Schiff and colleagues,[493] the lymph node enlargement usually lasted between 5 and 8 days. In two outbreak studies involving adolescents and young adults, posterior auricular and suboccipital lymphadenopathy was noted in all patients with rash.[180,231] In contrast to these findings, Landrigan and associates[324] noted that only 47 percent of children and 58 percent of adolescents had similar lymph node enlargement during epidemic rubella illness. Although a frequent suggestion is that the finding of exanthem and suboccipital lymphadenopathy is pathognomonic for rubella, this suggestion is incorrect. In young children, similar involvement is seen frequently with enteroviral and adenoviral infections. In adolescents

and young adults, the association more strongly indicates rubella, but infectious mononucleosis, *Mycoplasma pneumoniae* infection, acquired toxoplasmosis, and other possibilities also must be considered.

The occurrence of fever in rubella varies; when it does develop, the temperature usually is elevated only minimally. In children with experimentally induced rubella, Krugman and Ward[318] noted that 5/13 had temperatures of 38° C (100.4° F) or higher. Two children had maximal temperatures of 38.5° C (101.6° F). Schiff and colleagues[493] noted that all 9 infected volunteers had fever with a median duration of 5 days. Landrigan and associates[324] found fever in 74 percent of children and only 47 percent of adolescents; Gross and coworkers[231] observed fever in only 6/17 adolescents. On occasion, children with apparent rubella have been noted to have markedly elevated temperatures. Few such cases have undergone virologic study, so some doubt must be raised regarding whether the illnesses were induced by rubella virus or were caused by other viral agents more commonly associated with marked febrile responses, such as enteroviruses and adenoviruses. I have seen an 8-year-old boy with virologically and serologically confirmed rubella with a temperature of 40° C (104° F) on the day before the appearance of his rash. The 14-month-old girl with arthritis described by Hildebrandt and Maassab[266] had a temperature as high as 40.5° C (105° F).

In 1898, Forchheimer[184] described what he thought was the enanthem of German measles. He described pinhead-sized macular lesions with a rose-red color on the soft palate and uvula that appeared at approximately the time of the exanthem and lasted less than 24 hours. This exanthem has not been identified in children I have examined; however, petechial lesions on the soft palate and uvula have been seen occasionally. Mild pharyngitis is not an uncommon occurrence. Other signs and symptoms in rubella include mild conjunctivitis, sore throat, coryza, cough, and headache.

The duration of illness in uncomplicated rubella varies considerably. Most patients would continue normal activity if the rash were not present. In general, full return to normal activity occurs within 3 days. A small number of adults are bothered by persistent headache, eye pain, and pruritus for 7 to 10 days.

The white blood cell count in rubella tends to be low. Schiff and colleagues[493] found leukopenia in all nine volunteers. In these subjects, leukopenia paralleled the pattern of fever, with onset occurring 24 hours before the rash was manifested and persisting for 4 to 5 days. Before rubella could be confirmed by both specific serologic and virologic methods, many experts thought that rubella could be confirmed accurately by characteristics of the white blood cell count.[268,220] Leukopenia was found at the onset of disease; the total count rose to a high-normal value during a 10-day period. Relative neutropenia was noted by Hynes[289] in many patients; one patient had a neutrophil count of 868 cells/mm^3 on the first day of illness. Plasma cells, Türk cells, or both were noted in acute rubella in all cases studied by Hynes[289] and Hillenbrand.[268] A Türk cell is a developing plasma cell that is 25 to 40 µm in diameter and contains a 15- to 30-µm nucleus. The nucleus has two to five prominent nucleoli and a well-defined, light reticulum. The cytoplasm often is vacuolated. Twenty-five percent of the patients studied by Hynes[289] had elevated erythrocyte sedimentation rates during the first week of illness.

Complications

Joint Involvement. The incidences of reported cases of arthritis and arthralgia vary considerably across studies.* In general, both arthralgia and arthritis occur more commonly in adults than in prepubertal children. Women are afflicted more often than are men. In a large outbreak in Bermuda in 1971, 42 percent of 125 patients studied complained of joint pain or discomfort.[298] Three patients had swelling of the joints. The prevalence of joint symptoms increased from 18 percent in the 0- to 9-year-old age group by approximately 20 percent increments per decade; 73 percent of those older than 30 years had symptoms. Joint complaints generally were more common in females than in males older than 10 years of age. This difference was most marked in the 10- to 20-year-old age group. Landrigan and associates[324] studied the location of joint symptoms in adolescents and found that the fingers were involved most often; the knees and wrists also were implicated commonly.

Yanez and associates[625] studied 11 patients with rubella arthritis. In all instances, multiple joints were involved. The onset of arthritis occurred 1 to 6 days after the beginning of the exanthem and lasted 3 to 28 days (mean, 9 days). The erythrocyte sedimentation rate was elevated in three of seven cases, and one patient had markedly positive latex test results. The white blood cell count was below 5000 cells/mm^3 in five of seven patients. One woman had bilateral carpal tunnel syndrome. Four children with transient carpal tunnel syndrome accompanying rubella virus infection have been described.[46] Panush[420] noted serum hypocomplementemia with rubella arthritis in a 25-year-old woman.

The possibility that rubella viral infection is related to rheumatoid arthritis has been studied on several occasions.† Martenis and colleagues[353] described a 21-year-old woman in whom rheumatoid arthritis developed after typical rubella with arthritis. Deinard and associates[142] found that all serum specimens from 80 patients with rheumatoid arthritis contained rubella HI antibody. In contrast, only 86 percent of an equal number of nonarthritic controls and a group of persons with other forms of arthritis had measurable rubella antibody titers. Ogra and associates[410] noted that patients with juvenile rheumatoid arthritis had IgM and IgG serum rubella antibody levels that were four to six times higher than those observed in controls during rubella infection. They also noted specific staining for rubella virus antigen in the synovial fluid of 33 percent of these patients with juvenile rheumatoid arthritis. Grahame and associates[221] repeatedly recovered rubella virus from the synovial fluid of six patients with inflammatory oligoarthritis or polyarthritis during a 2-year period.

†References 14, 22, 52, 353, 410, 417.

Neurologic Manifestations. Encephalitis is a rare complication of rubella.* Sherman and colleagues[518] noted six cases of encephalitis in an epidemic during the spring of 1964 that involved approximately 30,000 children. This rate of encephalitis (1/5000 cases) is similar to the rate of 1/6000 noted in Detroit in 1942.[352] Rubella encephalitis is clinically similar to encephalitis from measles virus infection but is thought to be less severe. Overall, it is estimated that rubella encephalitis mortality is approximately 20 percent.[179] However, mortality and morbidity rates have varied considerably. Although rubella encephalitis is a rare complication of rubella infection, rubella should still be considered in the differential of encephalitis in unvaccinated individuals. Sherman and colleagues[518] noted that three of six children studied in Pittsburgh died of this complication during the spring of 1964, whereas in Atlanta during the same epidemic period, six patients recovered uneventfully. Rubella encephalitis generally is a self-limited illness with a favorable prognosis. Of survivors, 80 percent tend to recover without any permanent sequelae.[233] Guler and colleagues[233] report a case of rubella encephalitis from Turkey in a 9-year-old unvaccinated boy admitted with headache, fever, and loss of consciousness. He had bilateral retroauricular lymphadenopathy but never developed a rash. Serum and cerebrospinal fluid (CSF) rubella IgM antibodies were positive, and serum IgG became positive 3 weeks later.[233] Figueiredo and associates[179] report a case of rubella encephalitis from Brazil in an 18-year-old unvaccinated man who presented with fever, nausea, severe headache, confusion, aggression, and a generalized tonic-clonic seizure. Eight days earlier he had a rash and fever. Serum and CSF tested positive for rubella virus IgM and IgG antibodies. Rubella virus was also isolated and confirmed with polymerase chain reaction (PCR) positivity from CSF and peripheral blood mononuclear cells. Phylogenetic analysis showed that it was rubella virus of the 1a genotype.[179]

The onset of encephalitis usually occurs 2 to 4 days after the rash appears, but occasionally, rash and neurologic symptoms occur at the same time; in other instances, the appearance of encephalitis is delayed as much as 1 week after the onset of illness. Examination of CSF usually reveals mild pleocytosis (20 to 100 cells/mm^3), with most cells being lymphocytes. The protein content is normal or slightly elevated, and the sugar concentration is normal.

Kenny and associates[306] studied seven survivors of rubella encephalitis 1 year after their illnesses and could find no significant loss of intellectual function. Five of the seven had abnormalities on electroencephalography, and two patients had minor neurologic abnormalities. Gibbs and colleagues[211] found abnormal electroencephalographic tracings in 6/45 children with uncomplicated rubella.

Other neurologic complications associated with rubella include progressive panencephalitis, carotid artery thrombosis, myelitis, optic neuritis, Guillain-Barré syndrome, and peripheral neuritis.* Figueiredo and colleagues[178] also report a case of Guillain-Barré syndrome associated with rubella from Brazil. They reported an 18-year-old woman with fever, emesis, headache, neck pain, arthralgias, paresthesias, progressive weakness of her lower limbs, and left-sided facial paralysis. Six days earlier she had rash, fever, cervical lymphadenopathy, and hepatomegaly. Rubella virus, again genotype 1a, was isolated from CSF and peripheral blood mononuclear cells. Serum IgM and IgG and CSF IgG antibodies against rubella were positive.[178]

Of particular interest is the common occurrence of numbness, tingling, and other symptoms consistent with neuritis during rubella infection. Cuetter and John[131] studied 20 patients with complaints of neuritis accompanying rubella and could find no objective sensory deficits or nerve conduction abnormalities.

Wolinsky and colleagues,[619] Lebon and Lyon,[333] and others have described a slowly progressive and fatal nervous system disorder with rubella that was similar to subacute sclerosing panencephalitis. This illness has occurred as a late manifestation of congenital rubella and also has occurred in children who acquired their initial infection in childhood.[56]

Thrombocytopenia. Thrombocytopenic purpura occurs in rubella at an incidence of 1/3000 cases.[33] Children are afflicted more frequently than adults, and girls are affected more often than boys.† The median interval between the onset of exanthem and the occurrence of purpura is approximately 4 days. On occasion, rash and purpura develop simultaneously; often, however, the hemorrhagic manifestations do not become apparent until 2 weeks after the exanthem develops. The illness usually is self-limited, but its duration varies from a few days to several months; although deaths caused by hemorrhagic complications have occurred, recovery is the general rule.

Other Complications. Myocarditis and pericarditis are rare complications of rubella.[201] A 30-year-old woman was noted to have erythema multiforme exudativum and arthritis with apparent clinical rubella.[198] In an outbreak that involved 46 military recruits, testicular pain was a complaint in 25 percent.[496]

During a rubella epidemic in Japan in 1976 in which 79 patients were studied, 71 percent were noted to have mild catarrhal or follicular conjunctivitis.[246] Six patients had epithelial keratitis that persisted for 2 to 7 days. Seventeen patients had preauricular lymph node swelling in association with their eye findings. During the same epidemic, 13 cases of hemolytic anemia (including 2 cases of hemolytic-uremic syndrome) were noted after the patients had infection with rubella virus.[575] During an epidemic of rubella in Japan, Sugaya and colleagues[547] found that 7.5 percent of 241 patients had liver involvement.

†References 24, 33, 235, 295, 345, 393, 419, 536, 599.

Rubella has been noted to cause hepatitis in congenital rubella infections as well as in acute infections in both children and adults. Previously, severe hepatitis secondary to rubella had been noted only in neonatal rubella infections. However, Figueiredo and colleagues[177] report for the first time a case of acute liver failure necessitating liver transplant that was associated with rubella virus infection in a child. Serum IgM and IgG antibodies against rubella were positive, and peripheral blood mononuclear cells showed cytopathic effects characteristic of rubella. The rubella virus genome was also detected in liver fragments, and rubella virus antigen was found in the cytoplasm of hepatic cells, which suggests that the virus was replicating in hepatic tissue. The genotype of rubella virus identified was 1a. Through this case report, it is suggested that rubella can be an unrecognized cause of acute liver failure in children and should be included in the differential even if there is no prior exanthem history.

Rubella virus also has been reported to cause uveitis. De Visser and associates[141] report that rubella virus can cause a clinical spectrum of ocular symptoms that are similar to those of Fuchs heterochromic uveitis (FHU) and may be involved in the pathogenesis of FHU. Ruokonen and colleagues[477] and Suzuki and associates[548] have shown a strong association between FHC and intraocular antibody synthesis against rubella virus.

Congenital Rubella

From Gregg's original observation in 1941 of congenital defects in babies born to mothers who had rubella during early pregnancy until the pandemic of 1964, congenital rubella syndrome was considered to include only some combination of abnormalities involving the eyes, ears, brain, and heart. However, observations in 1964, supported by new virologic and serologic techniques, revealed a far more complex congenital rubella syndrome picture, and rubella syndrome was expanded to include many new anatomic findings and to acknowledge the reality of chronic persistent infection.

Congenital rubella is the result of in utero fetal infection, which usually occurs during the first 12 weeks of pregnancy. The fetal infection generally is subacute or chronic and may result in abortion, stillbirth, congenital malformations, active processes at birth (e.g., thrombocytopenia, encephalitis, or hepatitis), and, rarely, infected infants without defects. Table 173-5 summarizes the clinical findings in congenital rubella, an estimation of their frequency, and their main characteristics.

General: Infant Death and Growth Restriction

The most common manifestation of congenital rubella, readily apparent at birth, is generalized restriction of growth.* Between 50 and 85 percent of all babies weigh less than 2500 g, although gestational age is normal. Virtually all babies with intrauterine growth restriction have one or more other stigmata of congenital rubella. After birth, babies with intrauterine growth restriction often demonstrate continued growth restriction. In some instances, the failure to thrive is severe. Others show a normal growth pattern, but the child is proportionally small. The mortality rate of children with congenital rubella is high during the first year of life, with death specifically related to congenital pneumonia, heart defects and myocarditis, hepatitis, thrombocytopenia, encephalitis, immune deficiency, and failure to thrive.

Eye Findings

Approximately a third of all babies with congenital rubella have cataracts.* Cataracts may be bilateral or unilateral and are either central in location with a surrounding clear zone or diffuse. In most instances, cataracts are present at birth, but occasionally they are not observed until later in infancy. Retinopathy consisting of pigmentary defects occurs commonly in congenital rubella and is useful diagnostically, but it rarely adversely affects visual acuity. Microphthalmos occurs relatively frequently and usually is unilateral. Cataracts frequently are associated with microphthalmos.

Congenital glaucoma occurs in approximately 5 percent of congenitally infected infants. This defect usually is present at birth, but it often is overlooked. Diagnosis must be established early if sight is to be preserved.

Auditory Defects

Sensorineural deafness is the most common manifestation of congenital rubella; almost all patients have some degree of hearing impairment.† The hearing loss usually is bilateral but may be unilateral. Frequently, the only manifestation of congenital infection is deafness. An important note is that deafness is overlooked frequently in infancy, and children incorrectly are considered to be developmentally delayed. All children born to mothers who had rubella during the first half of pregnancy should undergo evaluation of their hearing several times during the first 5 years of life, regardless of whether they have other manifestations of congenital infection.

Neurologic Findings

Between 10 and 20 percent of all infants with congenital rubella have active meningoencephalitis at birth.‡ Manifestations of this infection include one or more of the following: a full anterior fontanelle, irritability, hypotonia, seizures, lethargy, and head retraction and arching of the back. Examination of the CSF reveals elevated protein and mild pleocytosis. Later neurologic disease, such as

TABLE 173-5 **Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection**

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
General			
In utero death	10-30	Spontaneous abortion; stillbirth	225, 251, 480
Intrauterine growth restriction	50-85	Generalized effect	106, 189, 191, 251, 254, 281, 314, 337, 347, 364, 441, 475, 476, 494, 524, 560
Extrauterine growth restriction	10	Failure to thrive	254, 337, 364, 374, 423, 560
Neonatal and infant deaths	10	Resulting from pneumonia, heart disease, hepatitis, thrombocytopenia, failure to thrive, immune deficiency, encephalitis	121, 225, 251, 314, 476, 494, 560
Eye			
Cataracts	35	Present at birth	20, 36, 49, 121, 191, 210, 225, 251, 254, 281, 313, 314, 364, 395, 476, 488, 494, 523, 560, 572, 574
Retinopathy	35	Present at birth; usually does not cause problems with vision	49, 113, 120, 210, 225, 251, 281, 315, 316, 367, 572, 574
Microphthalmos	5	Usually associated with cataract	49, 166, 210, 281, 314, 476, 504, 560
Glaucoma	5	Usually present at birth	49, 120, 251, 254, 281, 314, 476, 504, 514
Cloudy cornea	Rare	Usually present at birth; resolves spontaneously	49, 254
Severe myopia	Rare	Usually present at birth; defect may progress	116
Hypoplasia of the iris	Rare	Present at birth	49, 474
Strabismus	5	Associated with other eye defects	255, 364, 408
Iridocyclitis	Rare	Transient; associated with other eye defects	523
Auditory			
Nerve deafness	80-90	May be bilateral or unilateral; moderate or severe; often not recognized early	20, 51, 143, 166, 191, 225, 234, 251, 254, 322, 364, 380, 429, 435, 494, 514, 572, 574, 579
Central deafness	5	Often associated with other central nervous system defects	251
Middle ear damage	5	Usually associated with nerve deafness	463
Intraoral, Nasal, and Facial			
Cleft palate or lip	Rare		166, 225, 494
Dental abnormalities	Rare		72, 234, 364
Micrognathia	Rare		279, 494
Chronic rhinitis	Rare	Transitory finding	436
High-arched palate	Rare		251
Neurologic			
Motor defects	10	Associated with mental and other neurologic defects	364, 514, 627
Hyperirritability (tremors)	Rare	Transitory finding	468
Microcephaly	Rare		20, 254, 281, 364, 514, 560, 597, 612
Mental disabilities	10-20	Associated with other stigmata	116, 225, 248, 251, 362, 514, 546
Full anterior fontanelle	10	Transitory finding related to meningoencephalitis	117, 476
Meningoencephalitis	10-20	Transitory finding but may last for 1 year	144, 254, 313, 314, 435, 476, 523, 560
Spastic diplegia and quadriparesis	Rare	Associated with other stigmata	117, 144

TABLE 173-5 **Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection** (Continued)

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Seizures	Rare	Frequently transitory and related to meningoencephalitis	144, 252, 364, 435
Hypotonia	Rare	Transitory defect	143, 144
Brain calcification	Rare		430, 432, 523, 600
Cerebral arterial stenosis	Rare		248
Anencephaly	Rare		494
Encephalocele	Rare		494
Meningomyelocele	Rare		546
Behavior disorders	10-20	Frequently related to deafness	117, 144
Central language disorders	5		173, 225, 605
Autism	5		116, 173, 248
Aqueductal occlusion or hydrocephalus	Rare		225, 483
Poor balance	Rare		143, 627
Progressive panencephalitis	Very rare	Has onset during adolescence	569, 604
Cardiovascular			
Patent ductus arteriosus	30	Frequently associated with other defects	20, 36, 167, 191, 251, 254, 258, 296, 313, 388, 514, 523, 560, 574, 601
Pulmonary arterial hypoplasia, supravalvular stenosis, valvular stenosis, and peripheral branch stenosis	25	Frequently associated with other defects	191, 251, 254, 258, 296, 514, 521, 574, 601
Aortic stenosis	2-5		189, 258, 520, 591, 601
Ventricular and atrial septal defects	2-5		36, 514, 574, 601
Tetralogy of Fallot	2-5		166, 254
Myocarditis and myocardial necrosis	10		6, 166, 314, 388, 560, 601
Intimal fibromuscular proliferation of many arteries	5		165
Ventricular aneurysm	Rare		220
Pulmonary			
Interstitial pneumonitis	5-10	May be acute, subacute, or chronic	48, 166, 254, 313, 314, 388, 430, 432, 435, 494, 523, 560, 612
Tracheoesophageal fistula	Rare		494
Respiratory distress	Rare	Secondary to acute pneumonia	364
Gastrointestinal			
Esophageal atresia	Rare		494
Hepatitis	5-10	Associated with other evidence of disseminated disease	20, 166, 168, 254, 387, 539, 560
Obstructive jaundice	5		313, 314, 388, 468, 523
Chronic diarrhea	Rare	Related to failure to thrive and immune deficiency	435, 560
Pancreatitis	Rare	May lead to diabetes in later life	65, 152
Duodenal stenosis	Rare		146
Jejunal or rectal atresia	Rare		166
Genitourinary			
Undescended testicle	Rare	Cause-and-effect relationship with rubella infection in doubt	364, 523
Polycystic kidney, ectopic kidney, renal agenesis, or bilobed kidney	Rare	Cause-and-effect relationship with rubella infection in doubt	165, 166, 367
Hypospadias	Rare	Cause-and-effect relationship with rubella infection in doubt	49, 191, 523
Duplication of ureter	Rare	Cause-and-effect relationship with rubella infection in doubt	36
Renal artery stenosis	Rare		363

Continued on following page

TABLE 173-5 **Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection** (Continued)

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Hydroureter and hydronephrosis	Rare	Cause-and-effect relationship with rubella in doubt	252, 430, 514, 523
Inguinal hernia	Rare	Cause-and-effect relationship with rubella in doubt	252, 430, 514, 523
Nephritis and nephrocalcinosis	Rare		523, 560
Testicular agenesis	Rare	Cause-and-effect relationship with rubella in doubt	166
Orthopedic			
Bone radiolucencies	10-20	Radiolucencies in metaphyses of long bones	254, 364, 430, 442, 451, 454, 475, 476, 506, 597, 608, 612
Pathologic fractures	Rare		474
Bone deformities	Rare		225, 344*
Clubfoot	Rare		494
Myositis	Rare	Transitory defect	531
Skin			
Dermal erythropoiesis (blueberry muffin syndrome)	5	Transitory defect; usually associated with severe disease	310
Chronic rash	Rare		72, 246
Dermatoglyphic abnormalities	5		4, 12, 448
Dimples	Rare		244
Endocrine			
Diabetes mellitus	Rare		188, 297, 365
Thyroid disorder	Rare		116
Precocious puberty	Rare		116
Growth hormone deficiency	Rare		446
Hematologic			
Thrombocytopenic purpura	5-10	Usually associated with severe disease with high death rate; transitory	20, 33, 36, 39, 120, 191, 254, 281, 314, 321, 364, 430, 435, 442, 451, 452, 475, 494, 514, 593
Hemophagocytic syndrome	Rare		34
Hemolytic anemia	Rare	Transitory	386, 430, 452
Hypoplastic anemia	Rare	Transitory	117, 321
Extramedullary hematopoiesis	5-10	Usually associated with severe disease	548
Immunologic			
Thymic hypoplasia	Rare		248
Dysgammaglobulinemia	Rare		111, 245, 441, 460, 524
Asplenia	Rare		280
Reticuloendothelial			
Generalized lymphadenopathy	10		117, 191, 246, 560
Hepatosplenomegaly	10-20	Usually associated with severe disease; transitory	36, 314, 442, 476, 494, 514
Genetic			
Chromosomal abnormalities	Rare	Cause-and-effect relationship with rubella not established	16, 407

*Cherry JD, unpublished data.

intellectual disabilities and motor retardation, can be related to the severity and persistence of the initial meningoencephalitis. Active central nervous system infection has been demonstrated for a year or more.

Behavior disorders occur commonly in children with deafness and often cannot be associated with apparent meningoencephalitis. Children with congenital rubella who have generalized retardation of growth and a proportionally small head often have normal intelligence. In contrast, the prognosis for mental development in a child with true microcephaly is poor.

Chronic progressive panencephalitis has developed in a small number of adolescents with congenital rubella, similar to measles-related subacute sclerosing panencephalitis.

Cardiovascular Findings

In severe congenital rubella with multisystem involvement, myocarditis occurs and often is a cause of death.* Of the structural defects of the heart, patent ductus arteriosus (PDA) has been previously reported to be the most common. Although it may be the only lesion noted, two thirds of patients have other lesions as well. Historically, pulmonary artery stenosis has been considered the next most common defect and may involve the main pulmonary artery or its branches. Pulmonary valvular stenosis is the third most frequent defect. Pulmonic valvular or arterial stenosis and PDA commonly occur together. However, a recent study by Oster and associates[415] that reviewed studies from 1941 to 2008 that used cardiac catheterization or echocardiography to evaluate cardiovascular malformations in congenital rubella syndrome reported different findings. They noted that branch pulmonary artery stenosis was actually more common (78%) than PDA (62%) in those patients who had been evaluated by catheterization. In addition, the combination of branch pulmonary artery stenosis and PDA (49%) was more frequently found than either branch pulmonary artery stenosis (29%) or PDA (13%) alone.

Other Manifestations

The other manifestations of congenital rubella can be separated into three categories: manifestations related to active persistent infection, structural defects, and delayed manifestations of congenital rubella.†

Manifestations Related to Active Persistent Infection. This category encompasses a broad constellation of clinical events that largely were unknown before the pandemic of 1964. Collectively, they frequently are called the *expanded congenital rubella syndrome* and include interstitial pneumonitis, hepatitis, nephritis, bone radiolucencies, myositis, dermal erythropoiesis, chronic rash, thrombocytopenic purpura, hemolytic and hypoplastic anemia, immunologic deficiency, generalized lymphadenopathy, hepatosplenomegaly, meningoencephalitis, and myocarditis. Most infants with the expanded rubella syndrome clinically have low birth weight, exanthem caused by thrombocytopenia or dermal erythropoiesis or both, hepatosplenomegaly, and jaundice. Radiographs usually reveal long-bone radiolucencies. Respiratory distress caused by both diffuse pulmonary disease and myocarditis occurs commonly, and meningoencephalitis usually is evident. The duration of chronic infection in these babies varies. Approximately 20 percent of survivors still are shedding virus at 1 year of age. Between 10 and 20 percent of babies with hepatosplenomegaly and thrombocytopenia die during the first year of life.

Structural Defects. Other than deafness, eye defects, and cardiac anomalies, which have been discussed previously, the association of other malformations with congenital rubella infection is less well established. Malformations such as tracheoesophageal fistula, jejunal atresia, inguinal hernia, and others recorded in Table 173-5 occur frequently without evidence of in utero infection. Because they are noted only sporadically in babies born after maternal rubella, they possibly are chance associations rather than cause-and-effect relationships.

Delayed Manifestations. Noted delayed manifestations of congenital rubella that were not present in early life are deafness, ocular damage, progressive rubella panencephalitis, and vascular effects such as hypertension.[511] Endocrine delayed manifestations noted in congenital rubella cases include diabetes, thyroid disorders, early menopause, osteoporosis, and even possible growth hormone deficiency.[136] Of particular importance is the association between endocrine abnormalities and autoimmunity.[110] In one study of 201 deaf adolescents with congenital rubella, 23.3 percent had positive thyroid microsomal or thyroglobulin antibodies, and, of these patients, 19.6 percent had thyroid gland dysfunction. Patients with congenital rubella have an increased incidence of insulin-dependent diabetes mellitus.[214] In a 40-year observation study of 280 Japanese patients with congenital rubella syndrome, only 3 of the patients developed insulin-dependent diabetes.[554] HLA associations with diabetes in congenital rubella syndrome have also been reported. In particular, HLA A1-B8, which has been associated with insulin-dependent diabetes, has been found in many patients with congenital rubella who have diabetes (44%).[274] A recent review of literature by Gale,[203] supports prior reports that congenital rubella syndrome predisposes to diabetes. However, Gale's review suggests that only 1% of patients with congenital rubella as opposed to 20 percent will end up developing diabetes.

Psychiatric disorders are also often found in patients with congenital rubella syndrome and may be seen in up to half of patients. Rates of intellectual disability have been reported to be as high as 42 percent, and 4.12 to 7.3 percent of patients with congenital rubella syndrome also may have autism. In addition, higher rates of psychosis have been found, as well as increased rates of behavioral problems, including impulsivity, self-injury, and aggression.[287]

DIAGNOSIS

Differential Diagnosis

Postnatally Acquired Disease

Because no pathognomonic finding in rubella exists, the clinical diagnosis in an individual case often is difficult to establish (see also Chapter 58). However, as with other exanthematous diseases, the key to establishing a

diagnosis is careful elicitation of historical data. Rubella is an epidemic disease with a high clinical rate of expression of exanthem. Therefore, it is unusual, when proper investigation is performed, not to find the contact case or other cases in the community. Season also is an important consideration. Rubella generally occurs in the winter and spring, whereas enteroviral exanthems, which are the greatest masqueraders in young children, occur mainly in the summer and fall.

The incubation period also is important in separating rubella from exanthems caused by common enteroviruses or respiratory viruses. In rubella, the incubation period is long (18 ± 3 days), whereas the period in the other illnesses usually is much shorter (3 to 7 days). Age also is important. Today, rubella mainly is an illness of adolescents and young adults, and enteroviral exanthems are uncommon findings in patients at these ages.

The nature of fever also is useful in establishing the diagnosis of rubella. Temperature higher than 38.5° C (101.5° F) is an unusual occurrence in rubella but common with enteroviral exanthems, measles, and *M. pneumoniae* infection. In general, a past history of rubella infection is not particularly reliable. However, if a past illness can be documented by year, season, and symptoms, accurate information may be obtained. Useful characteristics of the rubella exanthem are its mild, erythematous, maculopapular, and discrete nature; marked pruritus in adolescents and adults; and an acneiform appearance on the face in adolescents.

Although suboccipital and posterior auricular lymphadenopathy often is thought by some investigators to be pathognomonic, its presence in nonrubella exanthems often leads to undue concern. In general, in a young child, suboccipital and posterior auricular lymphadenopathy occurs as commonly with enteroviral illnesses as with rubella. In young adults, however, this lymphadenopathy is much more useful because the enteroviral differential consideration is less of a problem. Similar lymphadenopathy does occur with acquired toxoplasmosis, infectious mononucleosis, and *M. pneumoniae* infection. A major problem in the differential diagnosis in adults is allergy. However, fever (even low grade), lymphadenopathy, headache, and eye pain, which are common events in rubella, should occur rarely in contact or other simple allergies.

Congenital Rubella

Establishing the diagnosis of congenital rubella in infants with known maternal exposure generally is not difficult. However, examining an apparently normal child at periodic intervals during the first few years of life is important so that deafness and subtle neurologic defects are not missed. The diagnosis of congenital rubella after an uneventful pregnancy is more difficult to make. All babies with evidence of intrauterine growth restriction or stigmata suggestive of congenital infection should undergo virologic and serologic study for rubella as well as for other infectious agents. Determination of the amount of serum IgM also can be useful in the study of babies with intrauterine growth restriction or babies born to mothers in whom rubella or other infection was suspected to have occurred during pregnancy.[541] Values greater than 21 mg/dL during the first week of life strongly indicate congenital infection; normal values do not rule out congenital infection, however.

Specific Diagnosis

Postnatally Acquired Disease

Rubella viral infection can be diagnosed specifically by isolation of virus from nasal or throat specimens in AGMK or other sensitive tissue culture systems or by PCR[120,123]; by the observation of a significant change in value of HI, ELISA, immunofluorescence, CF, or neutralizing antibody in two sequential serum samples or by the demonstration of specific rubella IgM antibody in a single serum sample. Most often today, the diagnosis of rubella is attempted by the use of a single serum test for identifying rubella IgM antibody.* Commercial rubella IgM immunoassays are now available, and in general their sensitivity and specificity ranges vary from 75 to 95 percent and from 85 to 100 percent, respectively.[145,563] Determination of rubella-specific IgM antibody in saliva 7 to 42 days after the onset of illness also has been shown to be both sensitive and specific.[450] Although these tests are practical, one should realize that the specificity and sensitivity of all routinely used tests are not 100 percent accurate. False-positive results occur all too frequently and commonly lead to unnecessary interventions. When the diagnosis is critical, such as with suspected rubella in pregnancy, a wise approach is to study IgG antibody in paired sera collected 1 to 2 weeks apart in addition to determining IgM antibody. One of the problems encountered with diagnosing rubella infection with serum IgM antibodies is that only 50 percent of serum samples from rubella cases collected on the day of rash onset will be positive. Work by Abernathy and associates[1] compared detection of rubella IgM from sera and oral fluids with detection of rubella RNA from oral fluids by RT-PCR taken within 4 days after rash onset from suspected rubella cases during a rubella outbreak in Peru in 2004 to 2005. They found that RT-PCR testing of oral fluid confirmed more rubella cases than IgM testing of either serum or oral fluid during days 1 and 2 after rash onset. However, the methods confirmed approximately the same number of cases on days 3 and 4 after rash onset.

Unfortunately, a rise in IgG antibody titer and an IgM-positive test result can occur in reinfection, as well as in primary infection. Because reinfection in a pregnant woman is very unlikely to lead to damage to the in utero fetus, distinguishing primary infection from reinfection is important and can be done by measuring the avidity of rubella IgG antibody.[243,271,449] Rubella IgG avidity assays focus on the strength of antigen-antibody interaction, which can differ with first exposure to an antigen as with primary infection in contrast to previous infection. In primary infection, this antigen-antibody interaction is low (i.e., low avidity), whereas in reinfection or prior

*References 15, 25, 35, 37, 74, 93, 98, 126, 148, 163, 176, 186, 215, 277, 350, 370, 394, 425, 502, 525, 564, 585.

infections, this antigen-antibody interaction is stronger (i.e., high avidity).[516]

Congenital Rubella

The best method for establishing a definitive diagnosis of congenital rubella is viral isolation or PCR. Specimens for viral culture or PCR should be obtained from the nose, throat, urine, buffy coat of blood, and CSF. Because of transplacental passage of maternal IgG, establishment of the diagnosis of congenital rubella in the neonatal period by serologic methods is fraught with difficulty. Usually, specific rubella IgM antibody can be demonstrated with presently available techniques. In questionable cases, follow-up studies comparing infant and maternal antibody values often establish the diagnosis. If the infant's value is the result solely of transplacentally acquired antibody, it should drop fourfold to eightfold by the time the infant reaches 3 months of age and continue to fall to nondetectable values by 6 to 8 months of age. However, the antibody value in some congenital infections also may fall, so disappearance of antibody in serum does not rule out in utero infection completely. Also, in questionable cases, the study of IgG rubella antibody avidity may be useful.[264,449]

The retrospective diagnosis of congenital rubella in late infancy and the second year of life has been difficult to make. However, researchers have shown that affected children have low avidity of specific IgG antibody, and, therefore, a retrospective diagnosis of congenital rubella can be made by specific avidity assays.[264] Also useful for the serologic diagnosis of congenital rubella during the prenatal and newborn periods are rubella IgG peptide–based enzyme immunoassay and rubella immunoblot assay.[362] Newborns who were infected during the first 12 weeks of gestation have reduced levels of antibodies directed at both the linear E1 epitope (SP15) and the topographic E2 epitope.

Fetal rubella can be diagnosed in amniotic fluid samples by RT-PCR.[460,555]

Qualitative Demonstration of Rubella Antibody

The original screening method for rubella antibody was HI. Today, HI has been replaced by more rapid and easier tests involving enzyme immunoassay, erythrocyte agglutination, and latex agglutination. In general, all are both highly sensitive and specific.[97,175]

TREATMENT

Postnatally Acquired Disease

Uncomplicated Rubella

No specific therapy is necessary or indicated for uncomplicated rubella. Starch baths may be useful in adults with troublesome pruritus. Of importance is that affected patients understand that they are contagious and that transmission of infection to a pregnant woman could have serious consequences.

Complications of Rubella

On occasion, arthritis can be severe in adults. When weight-bearing joints are affected, rest is encouraged. Symptoms readily respond to aspirin therapy; corticosteroids are not indicated. In rubella encephalitis, care is supportive, with adequate maintenance of fluids and electrolytes.

Thrombocytopenia usually is self-limited; however, severe bleeding has occurred on occasion. Splenectomy is not indicated. Corticosteroid therapy often is used, but with little evidence of specific benefit in rubella-infected patients. In patients who do not recover rapidly and in those with severe bleeding, treatment with intravenous immunoglobulin should be considered.

Management of Exposed Pregnant Women

Ideally, all pregnant women should have received rubella vaccine previously or been shown to have rubella antibody by an appropriate serologic test. If a pregnant woman is exposed to a person with rubella and the history of previous immunization or antibody presence is unknown, an immediate blood specimen should be obtained and a rubella antibody test performed. If antibody to rubella is demonstrated, no action is necessary.

If IgG antibody is not detectable in pregnant woman exposed to rubella, she is not rubella immune. Thus, a second blood specimen should be obtained 2 to 3 weeks later and tested for rubella antibody concurrently with the first specimen. If this second test result is negative, a third blood specimen should be obtained 6 weeks after exposure and also tested again for antibody concurrently with the first specimen. A negative result in both second and third specimens indicates that infection has not occurred. However, a positive test result in the second or third specimen but not found in the first indicates seroconversion and provides evidence for recent rubella infection.[14] Susceptible rubella-exposed women should undergo careful clinical observation for fever, lymphadenopathy, or exanthem for a 4-week period. If illness occurs, a nasal specimen should be cultured for rubella virus and serum should be examined for rubella IgM antibody. A second serum specimen should be submitted for rubella antibody examination. If rubella antibody seroconversion is noted or specific IgM antibody is demonstrated, the risk for fetal infection and malformation is considerable. Because false-positive rubella IgM antibody test results are not rare occurrences, all tests that yield positive results should be repeated for confirmation (by another assay and in another laboratory if possible). Because IgM antibody can occur in reinfections and fetal risk is then minimal, determining the avidity of IgG antibody also may be useful.[243,271,449] The patient should be so advised, and therapeutic abortion should be discussed.

In situations of known exposure of a susceptible pregnant woman in which therapeutic abortion is not possible and exposure can be documented to have taken place within 72 hours, our opinion is that 20 mL of immunoglobulin should be administered immediately. The use of

immunoglobulin is controversial, but in certain controlled situations, it has been effective in preventing disease.[57,376,490,580]

Management of Pregnant Women with an Exanthem Thought To Be Rubella

In this circumstance, if previous rubella serologic study results are available, they are extremely useful. If previous serum antibody has been noted, the mother should be reassured that the present illness is not likely to be rubella. However, because false-positive rubella screening results do occur, a wise approach is to carry out rubella serologic study and, when possible, also viral culture. An acute-phase serum sample should be examined for rubella-specific IgM antibody. A second serum specimen should be collected 1 to 2 weeks after the disappearance of the rash. If rubella antibody has risen significantly or IgM antibody is demonstrated, it is highly likely that congenital infection has occurred and that anomalies may result. Again, a wise approach is to confirm IgM positive test results and, if available, do IgG rubella antibody avidity study. In this circumstance, the woman should be counseled about therapeutic abortion.

If a previous serum rubella antibody value is not available, a serum sample should be collected immediately and another collected 2 to 3 weeks later. These sera should be examined as paired specimens for rubella antibody and analyzed for specific rubella IgM antibody. If a rubella antibody rise is demonstrated or the presence of rubella IgM is noted, one must assume that rubella viral infection has occurred, and the patient should be advised about the risk for congenital infection and the possibility of therapeutic abortion.

Management of Children with Congenital Rubella

Isolation Procedures

Most babies with congenital rubella remain actively infected at the time of birth, are contagious, and therefore should be placed in isolation. Room isolation and urine precautions are the major necessities. The isolated baby should be cared for only by persons known to be seropositive for rubella. Because rubella viral shedding has been known to occur for a year or more in some babies, isolation of infants with congenital rubella should be continued for this duration unless repeated viral cultures have proved negative. Current specific recommendations from the 2012 *Red Book* indicate that contact isolation in the hospitalized patient is indicated for children with proved or suspected congenital rubella until they are at least 1 year of age, unless two cultures of clinical specimens obtained 1 month apart after 3 months of age are negative for rubella virus.[14]

After the child is discharged from the hospital, no special precautions are necessary in the household setting. However, the parents should be advised of the potential risk to pregnant visitors.

Neonatal Period

As noted, the clinical manifestations of congenital rubella are varied, and in many infants, no symptoms are manifested during the first few months of life. In these apparently asymptomatic infants, no particular management problems are encountered. In other neonates, symptoms of continued viral infection are readily apparent and frequently are severe. In these infants, the following findings are important: pneumonia, thrombocytopenia, eye findings, heart defects, hyperbilirubinemia, and hepatosplenomegaly.

Although purpura and petechiae secondary to thrombocytopenia may be impressively severe in these infants, true hemorrhagic difficulties have not been a major problem. Corticosteroid therapy does not seem to be indicated, but considering treatment with intravenous immunoglobulin might be worthwhile. Careful evaluation of the eyes is important. Of immediate concern is the search for corneal clouding because its presence probably indicates infantile glaucoma. Cataracts and retinopathy also should be sought carefully. Infants with glaucoma should be referred immediately for ophthalmologic evaluation and therapy. Children with cataracts or retinopathy also should be referred, but therapy for cataracts is best delayed until the child reaches a later age.

Respiratory distress secondary to extensive viral involvement should be managed similar to other neonatal respiratory disease—assisted ventilation and careful attention to arterial blood gas values and pH. Although jaundice secondary to congenital rubella infection rarely is severe, standard criteria for the treatment of hyperbilirubinemia should be followed. Hepatosplenomegaly may be marked in some instances but is of no therapeutic concern.

Cardiac evaluation should be the same as in affected infants without rubella. Specifically, congestive cardiac failure should be treated vigorously; in malignant conditions (patent ductus arteriosus, coarctation of the aorta), lifesaving surgery should be contemplated.

Long-term Problems

Deafness. Hearing disability is the most frequent abnormality after infection with congenital rubella; more than 80 percent of infected infants have some degree of hearing disability. In many instances, deafness is the only clinical manifestation of congenital rubella, and because the establishment of this diagnosis in early infancy is difficult, the diagnosis frequently is delayed. However, early diagnosis of deafness and institution of proper educational programs are the most productive measures in the long-term management of children with congenital rubella. All too frequently, poor medical advice has been responsible for the delay in making an appropriate diagnosis and providing therapy. Any time that a mother suspects that her child is deaf, specific audiometric testing should be performed. Many general practitioners, pediatricians, and even otolaryngologists think that hearing cannot be tested in infants. This concept must be discouraged vigorously; at proper centers, a severely deaf child can be recognized in virtually all instances.

If deafness is diagnosed, the child should be referred immediately to a training program. Information about training programs can be obtained from the Alexander Graham Bell Association for the Deaf* and the John Tracy Clinic.† In virtually all instances, severely deaf children should be enrolled in an education program before or during the second year of life and the child should be fitted with a proper auditory amplification device. Although deafness in congenital rubella is sensorineural, a surprising finding is that conduction defects also are noted in many older children. For these children, other aspects of otolaryngologic care may be indicated.

Eye Problems. All children with eye problems (i.e., cloudy cornea, glaucoma, cataracts, retinitis, or strabismus) should be referred at an early age for ophthalmologic evaluation. Glaucoma requires immediate attention. Decisions about cataract surgery should be left to the discretion of the ophthalmologist but, in general, are well deferred until after the end of the first year. Retinopathy, although frequently impressive on ophthalmoscopic examination, rarely causes much visual defect. Strabismus is managed as it is in children without rubella. Advice on eye problems in congenital rubella can be obtained from the American Foundation for the Blind.‡

Heart Problems. Congenital heart disease secondary to in utero rubella infection should be managed as heart disease is in children without rubella. Of importance is that the children be referred to cardiac centers where sophisticated diagnostic techniques and cardiac surgery facilities are available for correctable lesions.

Musculoskeletal Problems. Isolated musculoskeletal defects are relatively uncommon findings in congenital rubella. However, when the symptoms indicate, referral to a cerebral palsy clinic is useful, both for specific therapeutic modalities and for the camaraderie of group therapy for the children as well as the parents.

Central Nervous System Problems. Careful analysis of the available data suggests that many infants who have been labeled intellectually disabled actually are children with auditory or visual defects who have not had proper diagnosis and training for their handicaps. No child with congenital rubella should be labeled mentally subnormal until extensive audiologic and ophthalmologic investigations and perhaps specific therapy have been performed.

Immunologic Defects. A small number of children with congenital rubella have been noted to have specifically low levels of serum IgG. These infants have systemic continued viral infection and in general do poorly. Although outcome studies are not available, administration of immune serum globulin (intramuscular or intravenous immunoglobulin) to these infants periodically seems prudent.

Multiple Handicaps. All too frequently, children infected in utero with rubella virus suffer from one or more of the handicaps mentioned. Care of these infants and children requires many different resources and modalities of therapy. Frequently, the physician is the one who must coordinate both the diagnostic and the long-term educational efforts that are necessary for optimal progress of an affected child. In addition to the Alexander Graham Bell Association for the Deaf, the John Tracy Clinic, and the American Foundation for the Blind, already mentioned, the following agencies may be helpful to physicians or the parents of congenital rubella children: United Cerebral Palsy Research and Educational Foundation,* Easter Seal Research Foundation,† The Arc of the United States,‡ and Maternal and Child Health Division, Department of Health and Human Services,§

PREVENTION

Active Immunization: Live Attenuated Rubella Virus Vaccine

In 1969 three rubella vaccines were licensed for use in the United States: HPV-77: DE-5 (duck embryo), HPV-77:DK-12 (dog kidney), and GMK-3:RK33 Cendevax (rabbit kidney) strains.[603] The HPV-77:DK-12 vaccine was later removed from usage because a higher rate of joint complaints were noted after vaccination with this strain. In 1979 the RA 27/3 (human diploid fibroblast) strain (Meruvax-II) was licensed for use in the United States. At present, the RA 27/3 rubella virus vaccine is the only vaccine currently licensed for usage in the United States. The RA 27/3 rubella vaccine is a live-attenuated virus vaccine. The virus used was first isolated from a rubella-infected aborted fetus from the Wistar Institute in 1965. Attenuation of the virus was achieved by 25 to 30 passages in tissue culture, using human diploid fibroblasts. This vaccine does not contain any duck, chicken, or egg protein. The rubella vaccine currently is available in combination with measles and mumps vaccines as MMR or combined mumps, measles, and varicella vaccine as MMRV (ProQuad). Currently, the single-antigen rubella vaccine is not available for usage in the United States. Both the MMR and MMRV vaccines are distributed as a lyophilized (freeze-dried) powder and require reconstitution with sterile, preservative-free water. These vaccines both contain

trace amounts of human albumin, neomycin, sorbitol, and gelatin.[89] Vaccination can be expected to produce antibodies in more than 95 percent of those immunized.* Antibody titers after RA 27/3 vaccination are slightly lower than those after natural infection, but they have been demonstrated to persist for an 11- to 15-year period with a pattern similar to that occurring after natural infection, even in the absence of reexposure to rubella virus.[46,284,438]

Because of universal immunization practices, indigenous rubella has been eliminated in the United States and more recently from the Americas.[70,86,88,455,457] Finland's vigorous two-dose immunization program also resulted in the elimination of indigenous rubella.[428,429]

Recommendations for Use

For complete information about rubella immunization, the reader is referred to the most recent recommendations of the Immunization Practices Advisory Committee of the U.S. Public Health Service,[80,85] the recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics,[13] and the vaccine manufacturer's product information.

Rubella vaccine is recommended for all children 12 months of age or older, adolescents, and adults, particularly women, unless otherwise contraindicated. Vaccination of children protects them from rubella and thus prevents them from subsequently spreading it. Vaccination of susceptible postpubertal women confers individual protection from rubella-induced fetal injury. Vaccination of adolescents or adults in population groups such as those in colleges, places of employment, or military bases protects them from rubella and reduces the chance of epidemics occurring in partially immune groups.

Rubella vaccine should not be administered to infants younger than 1 year of age because persisting maternal antibodies may interfere with seroconversion. When rubella vaccine is part of a combination vaccine that includes measles antigen, it should be administered to children approximately 12 to 15 months of age. A second dose of rubella-containing vaccine is recommended at school entry, typically at age 4 through 6 years.[89] Children who have not received rubella vaccine at the optimal age should be vaccinated promptly. Because a history of rubella is not a reliable indicator of immunity, all children for whom vaccine is not contraindicated should be vaccinated.

Vaccination of all unimmunized prepubertal children and adolescents as well as of adult women in the childbearing age group must be emphasized. Because of the theoretical risk to the fetus, women of child-bearing age should receive vaccine only if they are not pregnant and understand that they should not become pregnant for 28 days after receiving the vaccination.[14,89]

Special attention also should be placed on targeted immunization of at-risk postpubertal males and females, especially college students, military recruits, recent immigrants, health care professionals, teachers, and child care providers. People born in 1957 or after who have not received at least one dose of vaccine or who have no serologic evidence of immunity to rubella should be immunized against rubella.[14] Educational and training institutions such as colleges, universities, and military bases should seek proof of rubella immunity (a positive serologic test result or documentation of previous rubella vaccination) from all students and employees in the childbearing age. Nonpregnant women who lack proof of immunity should be vaccinated unless contraindications exist.

For the protection of susceptible female patients and female employees, persons working in hospitals and clinics who might contract rubella from infected patients or who, if infected, might transmit rubella to pregnant patients either should have serologically demonstrated immunity to rubella or should receive the vaccine.

Routine premarital serologic testing for rubella immunity would enhance efforts to identify susceptible women before pregnancy. Prenatal or antepartum screening for rubella susceptibility should be undertaken and vaccine administered in the immediate postpartum period—before hospital discharge. Previous administration of anti-Rh_0(D) immunoglobulin (human) or blood products is not a contraindication to vaccination; however, 6- to 8-week postvaccination serologic testing should be performed for confirmation of seroconversion in those few who have received the globulin or blood products. Obtaining laboratory evidence of seroconversion in other vaccines is not necessary. Please refer to the 2012 *Red Book* updated guidelines for the minimum recommended interval for rubella vaccination after receiving immunoglobulin.

No evidence has shown that live rubella virus vaccine given after exposure prevents illness or that vaccination of a person incubating rubella is harmful. Because postexposure vaccination would theoretically prevent illness if administered within 3 days of exposure and protect a person in the event of future exposure, postexposure vaccination is generally recommended unless otherwise contraindicated.[14]

Adverse Reactions

Vaccination in young children rarely is associated with any symptoms. However, on occasion, mild fever, rash, lymphadenopathy, and upper respiratory tract symptoms have been observed. In children receiving the MMR or MMRV vaccines, fever has been noted to develop 6 to 12 days after immunization in approximately 5 to 15 percent of children. Rash may occur in approximately 5 percent of those immunized, and mild lymphadenopathy has been frequently observed. A twofold increase in febrile seizure risk has been noted in children vaccinated with the combined MMRV vaccine 5 to 12 days after immunization. In children 12 through 23 months of age, febrile seizures have been noted more frequently after administration of the MMRV vaccine (7 to 9/10,000) in contrast to the MMR and varicella vaccines (3 to 4/10,000) given separately. One additional febrile seizure

*References 23, 341, 438, 492, 530, 595, 600, 601.

may be expected to occur per approximately 2300 to 2600 of these children immunized with the MMRV vaccine.[14,293,311]

More severe reactions have been noted rarely in children but have been an occasional problem in adults. Most of these complications were reported in association with the previously available vaccines, but complications with the RA 27/3 vaccine also have been noted.[23,157] Particularly troublesome are arthralgia and arthritis.*

These symptoms occur most commonly in adults. Arthralgia and arthritis occur most commonly in adults and have been seen more often in women than men.[89] Joint pain, which is typically localized to smaller, peripheral joints, has been found in approximately 0.5% of young children. Joint involvement typically begins 7 to 21 days after immunization and generally is considered to be a transient reaction.[14,89] Arthralgia develops in approximately 25 percent of susceptible postpubertal females after they have received the RA 27/3 vaccination, and approximately 10 percent have been reported to have arthritis-like signs and symptoms.[41,230,444] Infrequently, chronic or recurrent arthralgia, sometimes with arthritis or neurologic symptoms, including paresthesias, carpal tunnel syndrome, and blurred vision, reportedly have developed in susceptible vaccinees, primarily adult women.[80,285,533] One group of investigators reported the frequency of chronic joint symptoms and signs in adult women to be as high as 5 to 11 percent[561-563]; however, other data from the United States and other countries suggest that such complications caused by RA 27/3 vaccine are rare or perhaps nonexistent.† Patients with juvenile idiopathic arthritis (JIA) have been shown to be safely vaccinated with the rubella vaccine. However, a case report from Korematsu and colleagues[312] describes an 11-year-old girl with systemic JIA, previously in remission for 4 years, who then developed an abrupt and severe relapse with congestive heart failure 5 days after receiving the rubella vaccine. The authors suggest that the exacerbation of the patient's systemic JIA may be secondary to molecular mimicry between the rubella virus and her JIA.

Other complications, mainly with vaccines other than RA 27/3, include polyneuropathies (catcher's crouch, carpal tunnel syndrome, neuritis, and myeloradiculoneuritis),‡ marked lymphadenopathy (Cherry JD, unpublished data, 1967-1976), vasculitis, and myositis.[247]

Geiger and associates[209] noted a persistent rubella virus infection in a 16-year-old boy with acute lymphoblastic leukemia in remission who was vaccinated. The virus was identified in the patient's peripheral blood mononuclear cells 8 months after immunization. In contrast, persistent infection could not be demonstrated in 10 children with symptomatic human immunodeficiency virus type 1 infection.[193]

Cheong and colleagues[96] report a fatal case of disseminated tuberculosis in a 14-year-old girl, which occurred immediately after a measles-rubella vaccination. Previously, the exacerbation of tuberculosis infection related to measles-rubella vaccine has been reported only in severely immunocompromised patients. Although natural measles infection has been known to potentiate other infections such as tuberculosis, no prior evidence has shown that measles-rubella vaccinations may accelerate the progression of tuberculosis.

Other adverse reactions that occur after immunization with MMR or MMRV have been primarily associated with the measles, mumps, and varicella components of the vaccine. In recent years, particular focus has been placed on the risk for immune thrombocytopenia purpura after MMR immunization.[190,351] Please refer to Chapter 244 for further detail of other adverse reactions associated with the MMR and MMRV vaccines.

Contraindications

Administration of live rubella virus vaccine is contraindicated in women who are pregnant; in individuals with altered immune states, such as immunodeficiency, leukemia, lymphoma, and generalized malignant disease; or in patients treated with high doses of corticosteroids (≥2 mg/kg/day or >20 mg/day for 14 days or more), alkylating drugs, antimetabolites, and radiation. Fever is not a contraindication to immunization, and children with mild illnesses such as upper respiratory tract infections may still receive immunizations. However, immunization should be delayed until recovery in cases of moderate to severe acute illnesses.[14,89] A personal or family (i.e., sibling or parent) history of seizures of any etiology is a precaution for MMRV vaccination because these children may have an increased risk for febrile seizures. This caveat does not apply for children vaccinated with MMR and varicella vaccines administered separately.[89] Rubella immunization also, in most instances, should be deferred after the administration of blood products, including immune serum globulin (see Chapters 244 and 245).

Inadvertent Rubella Immunization in Pregnancy

From January 1971 to April 1989, the CDC observed to term 321 known rubella-susceptible pregnant women who had been vaccinated with rubella vaccine within 3 months before or 3 months after conception.[80,181] Ninety-four women received HPV-77 or Cendehill vaccine, 1 received a vaccine of unknown strain, and 226 received RA 27/3 vaccine. None of the 324 infants born to these women had malformations compatible with congenital rubella, but five of the infants (fewer than ~2%) had serologic evidence of subclinical infection. From these data, the CDC estimated a 1.3 percent maximal theoretical risk for congenital rubella among women vaccinated with the RA 27/3 rubella virus vaccine within 1 to 2 weeks before and 4 to 6 weeks after conception.[14] Thus, women who may have been inadvertently immunized with rubella during pregnancy should be counseled extensively regarding these potential risks to the fetus. However, these observations of outcomes do not necessitate pregnancy

*References 19, 30, 105, 122, 223, 339, 391, 409, 443, 532, 553, 556, 557, 561-563, 596.

termination as a result of rubella vaccine receipt during pregnancy.[14]

Multiple other studies have investigated the risk for congenital rubella among women who have received the rubella vaccine during pregnancy and have confirmed the safety of this vaccine among pregnant women. Castillo-Solorzano and associates[71] collected data from 2001 to 2008 from more than six countries of 30,139 women who were pregnant or became pregnant within 1 month after receiving the rubella vaccine. Seventy infants (3.5%) showed positive rubella serology, but none of the infants had features of congenital rubella syndrome. The authors concluded that the maximum theoretical risk for congenital rubella syndrome after rubella vaccination of susceptible pregnant women was 0.2%. A large study by Soares and colleagues[529] from several states in Brazil investigated 22,708 women vaccinated during pregnancy and found 67 newborns (4.1%) showed evidence of congenital infection but none with congenital rubella syndrome. Da Silva e Sa and associates,[134] Sato and associates,[484] and Minussi and associates[381] reviewed cases from Brazil, finding low rates of congenital rubella infection (2%, 4.7%, and 6.7%), but no cases of vaccine-associated congenital rubella syndrome. Another, smaller study from 2006 in Argentina by Pardon and associates[421] also did not show evidence of congenital rubella syndrome in infants born to women unknowingly pregnant during their mass rubella vaccine campaign. Nasiri and colleagues[400] and Namaei and associates[398] looked at pregnant women inadvertently vaccinated with rubella during pregnancy during Iran's 2003 mass vaccination campaign and found no cases of congenital rubella syndrome.[292]

In conjunction with a nationwide measles-rubella vaccination campaign in 2001, the fetal risk associated with rubella vaccination during pregnancy was studied in Costa Rica.[21] The study involved 1191 mother and child pairs, and no adverse pregnancy outcomes or cases of congenital rubella syndrome occurred.

Passive Immunization

The use of immunoglobulin for the prevention of rubella has been controversial for many years.* However, our opinion is that its use is indicated in certain circumstances. As previously noted, the specific indication for immune serum globulin is for the prevention of rubella in a woman thought to be susceptible to rubella who is in the first 20 weeks of pregnancy. If the exposure can be documented clearly as one to a specific, single person with rubella and immunoglobulin is given within 72 hours of that exposure, both maternal disease and congenital infection likely can be prevented. On the other hand, if the exposure was more general (e.g., a schoolteacher exposed to a child or children in the school setting), the woman probably was exposed for a considerable time before she realized the exposure. Therefore, because immunoglobulin probably will be administered too late (well into the incubation period of her disease and after viremia), congenital infection is not likely to be prevented. The dose of immunoglobulin for the prevention of rubella during pregnancy is 20 mL intramuscularly.

*References 28, 55, 150, 226, 348, 356, 360, 376, 490, 580.

Quarantine and Disease Containment

Patients with rubella should not have contact with susceptible persons until the rash has disappeared. Containment of rubella is a vital part of the prevention policy in the United States today. Rubella is a reportable disease, and compliance is the obligation of all physicians and other health care professionals. Reporting cases of rubella enables public health workers to organize vaccination programs so that small outbreaks of disease can be prevented from developing into major epidemics. During an outbreak, those without evidence of immunity should be immunized or excluded from school or child care attendance.

CHAPTER 174

ALPHAVIRUSES

174A ■ EASTERN EQUINE ENCEPHALITIS

Theodore F. Tsai • Gail J. Harrison

Eastern equine encephalitis (EEE) is an arthropod-borne viral infection of humans, horses, and other vertebrates that occurs in North and South America. In North America, infections recur in highly focal, primarily coastal locations in association with the habitat of *Culiseta melanura*, the enzootic vector. In the United States, Florida continues to have the highest occurrence of human cases.[36] Birds are the amplifying hosts, and humans and horses are infected incidentally. Because it is a highly pathogenic virus in humans that may be disseminated in the population, it is considered a possible biologic agent, category B threat, that could be used against civilian populations.[53,59]

ETIOLOGIC AGENT

EEE virus is an antigenically distinct member of the *Alphavirus* genus in the *Togaviridae* family. On the basis of nucleotide differences, it has been inferred that EEE and Venezuelan equine encephalitis diverged 1000 to 2000 years ago, with a subsequent division of EEE virus into North American and South American varieties.[8,50,52] South American strains can be differentiated by monoclonal antibodies and by short-incubation hemagglutination-inhibition tests.

North American strains collected over a broad geographic and temporal span demonstrate remarkable genetic stability in one or two major lineages, with minor local divergences occurring within isolated geographic loci. South American strains are genetically heterogeneous. They have been isolated in northward-migrating birds captured in the United States, but they have never been shown to become established.

ECOLOGY

Equine cases have been reported as far north as Quebec, Ontario, and Alberta provinces; in South America, EEE viral activity has been reported from the Caribbean, Mexico, Guatemala, Honduras, Panama, Colombia, Venezuela, Peru, Guyana, and Brazil and as far south as Argentina.[5,9,25,58] The viral transmission cycles in the Caribbean and South America are not well characterized but apparently involve small mammals, birds, and *Culex (Melanoconion)* mosquitoes.[1,25]

In North America, the distribution of virus activity closely follows the distribution of freshwater swamps on the Eastern Seaboard, Gulf Coast, and other inland areas. Florida, with abundant fresh water wetlands, is the state in the United States with the most cases in humans.[36] The distribution of virus corresponds to the distribution of the principal enzootic vector, *C. melanura*.[11,21,25] *C. melanura* feeds nearly exclusively on birds, so various epizootic (bridging) vectors are responsible for infecting humans and horses.* Numerous species may be involved, including *Coquillettidia perturbans*, *Aedes sollicitans*, *Aedes vexans*, and *Aedes canadensis*.

Infection and viremia are subclinical in most native birds, whereas whooping cranes and exotic birds such as emus, house sparrows, ring-necked pheasants, Pekin ducks, and chukar partridges may become ill and die of infection.† Outbreaks resulting in thousands of deaths have occurred in commercial pheasant flocks, in some instances perpetuated by cannibalistic pecking or preening of persistently infected quills.[4] Illness and deaths in pigs, goats, calves, rodents, and other mammals also have been reported.[26,45]

C. melanura is found in and near freshwater swamps, where larval stages breed in acidic waters associated with mucky peat soils. These foci (from north to south) are found in upland red maple, coastal white cedar, and southern loblolly bay biotypes.[11,25]

The viral overwintering mechanism has not been elucidated, but the remarkable permanence of endemic foci is a strong argument for overwintering in local reservoirs, such as reptiles and amphibians.[11,34,35,38,45] Serosurveillance in amphibians and reptiles have shown snakes, including garter snakes, to have high seropositive and to support viremia with EEE virus, whereas frogs, turtles, and lizards had little or low rates of infection.[30]

EPIDEMIOLOGY

EEE is a rare sporadic infection; a median of three cases occurs annually in the United States[40] (Fig. 174A-1). The states with the highest rates of infection show an average annual incidence of less than 1 per 10 million

*References 20, 22, 29-31, 36, 38, 41, 42, 56.
†References 4, 13, 14, 42, 57, 62.

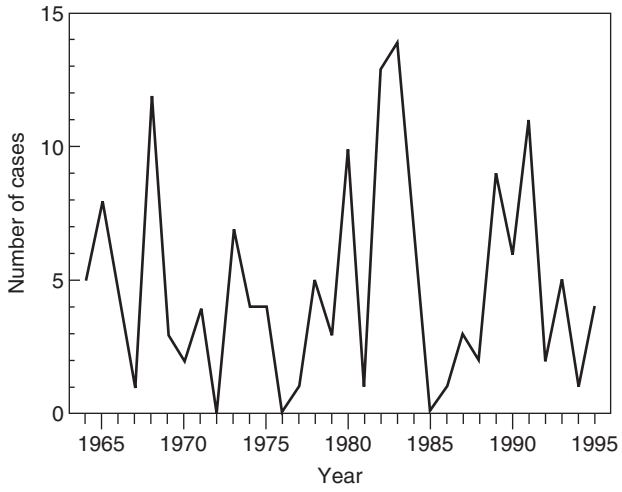

FIGURE 174A-1 ■ Reported cases of eastern equine encephalitis by year, 1964 to 1995.

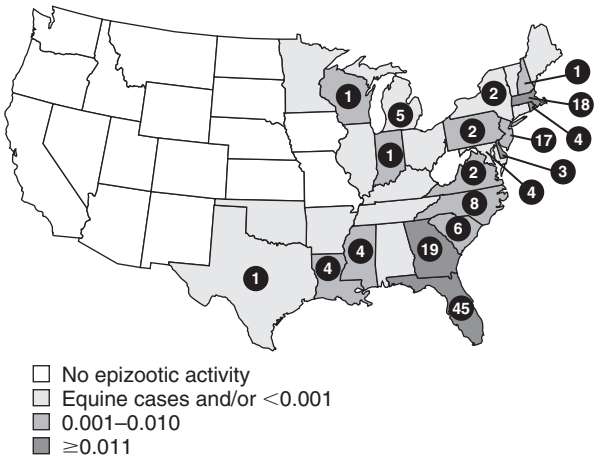

FIGURE 174A-2 ■ Reported cases and average annual incidence (per 100,000) of eastern equine encephalitis by state, 1964 to 1995.

(Fig. 174A-2). However, these estimates obscure the remarkably consistent and focal distribution of cases on the Atlantic and Gulf Coasts, from Ontario to Texas, and in isolated pockets of activity inland.[5,9,20] For example, until 1995, all human cases in Massachusetts had occurred east of Highway 495 in Essex, Norfolk, Plymouth, Bristol, and Middlesex counties; the six southernmost counties account for most of the epizootic activity in New Jersey; and foci of EEE viral activity recur in upstate New York counties near Syracuse, southwestern Michigan, northeastern Indiana, and northeastern Florida.[12,20,29,31,35] Outbreaks of human cases caused by North American viral strains have been reported from Jamaica, Trinidad, and the Dominican Republic.[6,17,18] Isolated epizootics with sporadic human cases have occurred in South America.[58] The unpredictability of risk is underscored by the occurrence of a case in a United Kingdom tourist who had a brief itinerary in Massachusetts.[32] Therefore, history of travel should be obtained in patients with possible EEE who are diagnosed in nonendemic areas.

Viral transmission, reflected in equine cases, occurs all year in Florida, although the peak incidence is from May to September.[7] Human cases have appeared as early as February and as late as December in Florida, with a peak occurring from June to August. In the Northeast, cases usually appear in late summer, from August to September, and as late as the third week in October.[40]

Cases occur chiefly at the extremes of age. However, serologic studies performed during a New Jersey outbreak disclosed that infection occurs with equal frequency in all age groups, thus indicating that biologic responses to infection rather than factors associated with exposure were responsible for the lower attack rates in young and middle-aged adults.[27] The ratio of inapparent infections to cases was highest in the middle years of life (29:1) and lowest in children younger than 4 years (8:1) and adults older than 55 years (16:1).[27]

Family clusters were observed in this epidemic and in the 1947 Louisiana outbreak.[33] In the New Jersey study, family members of cases had twice the rate of inapparent infections as the general population did; and in the southern Louisiana outbreak, two fatal cases and two seropositive members were observed in the same family.[27,33] Clusters of equine cases on a single premise are reported frequently.

Asymptomatic infections are uncommon occurrences, and long-term residence in an enzootic area leads to only a slight increase in population immunity. For example, even in an unusually active focus in southern New Jersey, only 7 percent of persons who had resided there 45 years or more had neutralizing antibody.[27] In serosurveys of endemic foci in Massachusetts, evidence of past infections was found in 0.5 to 0.7 percent of residents[51] and a postepizootic serosurvey of at-risk Connecticut pheasant farmers showed no evidence of infection.[43]

Specific behavioral risk factors have not been described; however, residence, travel, and outdoor activity near swampy habitats have been reported anecdotally as possible contributing factors.

CLINICAL MANIFESTATIONS

EEE is a fulminant encephalitis with rapid progression to coma and death in one third of patients. In infants and children, an abrupt onset of fever, irritability, and headache is followed closely by lethargy, confusion, seizures, and coma. The often desperately ill infants may have a bulging fontanelle, meningismus, high temperature, and generalized flaccid or spastic paralysis.[2,19,24,61,63] Some patients are evaluated initially for status epilepticus. The prodrome in adults and older children usually is brief, with nonspecific symptoms of fever, headache, and dizziness followed by clouding of the sensorium and rapid deterioration to coma. Remarkably, some patients have a prolonged prodrome lasting longer than a week, with a waxing and waning course of nonspecific symptoms, which may be associated with a better prognosis.[49,51,61] Various neurologic deficits have been described; in some cases, unilateral seizures, hemiparesis, hemiplegia, and aphasia have indicated focal areas of involvement.[16,46,49]

The peripheral leukocyte count usually is elevated with a shift to the left. White blood cell counts of 20,000/μL are typical, ranging as high as 60,000 with 55 to 89 percent neutrophils.[51] Cerebrospinal fluid (CSF) usually shows a polymorphonuclear pleocytosis with a total leukocyte count ranging from 500 to 2,000/μL. The initial neutrophilic pleocytosis of 60 to 100 percent may persist into the second week before shifting to a predominance of mononuclear cells.[52] CSF protein level is elevated and glucose concentration is reduced in most cases. Erythrocyte counts higher than 500/μL are found in some cases.

Imaging studies disclose only cerebral edema in three fourths of patients. However, focal rim-enhancing lesions and areas of low alteration with mass effect have been observed on computed tomographic scans in the frontal cortex, thalami, midbrain, and lentiform nuclei.[16,46,49] Isointense diffusion-weighted images and hyperintensity on apparent diffusion coefficient images early in the course of illness in one case suggested vasogenic edema in the T2-weighted hyperintense areas.[28] Magnetic resonance imaging also shows focal lesions in basal ganglia and thalami in patients with EEV.[18] Electroencephalographic tracings with focal or background slowing have been associated with a favorable outcome, whereas disorganized background activity, a burst-suppression pattern, and high-voltage delta slowing have been associated with a poor prognosis.[51]

Mild nonencephalitic illnesses usually are not diagnosed. However, in the 1959 outbreak in New Jersey, fever, headache, nausea, vomiting, and sore throat were common symptoms in 19 patients who had serologic evidence of infection. A third of the patients had illnesses sufficiently severe to motivate them to consult their physicians.[27] Other patients with bladder dysfunction, dysesthesias, weakness, and signs of myelitis have been described.[10,39] One case of infection during pregnancy has been reported. The third-trimester infection was severe, but the woman recovered from encephalitis and coma and was delivered of an apparently normal neonate. Serologic studies of the neonate's blood were not performed. Infection with EEV also was reported to trigger fatal hemophagocytic lymphohistiocytosis in an infant.[43]

PATHOLOGY

Pathologic changes in the brain are characterized by lesions in the cortical and deep gray matter, with varying degrees of neuronal loss from mild to extensive focal necrosis.[15,47] Viral antigen is found predominantly in neurons and only occasionally in astrocytes.[23] Rare viral particles have been identified by electron microscopy in principally extracellular locations.[3,37] Neutrophils predominate in cellular infiltrates in the meninges, vascular cuffs, and foci of tissue damage in the cortex and brain nuclei of patients dying acutely; at later stages, neutrophilic infiltrates are replaced by mononuclear cells.[3,15,23,47] Immunohistochemical examination of one patient disclosed a predominance of helper T cells in perivascular infiltrates, with some B lymphocytes. The most intense inflammatory reaction occurred in areas where antigen-positive neurons were absent, presumably where cell lysis already had occurred. Perivascular macrophages contained cleared viral antigen, but antigen could not be demonstrated in vascular endothelial cells.[23]

PATHOGENESIS

After peripheral inoculation of experimental animals, local viral replication occurs at a low level or may be undetectable. Viremia develops after this eclipse period, with disseminated infection of the spleen, liver, and kidneys noted in monkeys and guinea pigs and infection of the spleen, heart, and lungs observed in mice. Infectivity can be demonstrated in the brain only after viremia and infection in the viscera are established, thus suggesting that invasion of the central nervous system occurs by hematogenous spread.[47] Neurologic injury is associated with vasogenic edema in the earliest stages and subsequently with virus-induced cytolysis and host inflammatory responses.[28]

The immune response in humans presumably is similar to that observed in experimental alphavirus infections in mice, in which host resistance depends on rapid elaboration of a humoral immune response.

PROGNOSIS AND SEQUELAE

The case-fatality ratio is 33 percent among reported cases and is highest in the elderly; outcome is best in young adults aged 20 to 59 years, in whom the case-fatality rate is 24 percent.[35] Patients with a long prodromal illness (>4 days) have a better prognosis, which is consistent with the protective effect of a peripheral antibody response in the pre-neuroinvasive phase.[44]

Residual neurologic damage is observed more often in young children. In a Florida series, serious sequelae were seen in 4 of 7 survivors younger than 5 years and in 1 of 10 survivors in other age groups.[7] Similar findings were reported in a follow-up of epidemic cases in Massachusetts: 7 of 8 survivors younger than 3 years of age had neurologic sequelae, and only 1 of 4 surviving adults had residua.[2,21] Neurologic impairment ranged from mild unilateral spasticity to profound mental retardation, seizure disorders, and quadriplegia.

DIAGNOSIS

A specific laboratory diagnosis usually is made from serologic studies. Isolation of virus from CSF is unusual. The virus should be sought from brain biopsy tissue or autopsy material. EEE virus grows rapidly in a variety of cell lines, including Vero A549 and MRC-5 cells, and causes widespread cytopathic effect in several days.[55] Specific identification of viral isolates can be accomplished rapidly by immunofluorescent or immunoperoxidase techniques. EEE virus has been identified by immunofluorescence and by electron microscopy in brain tissue.[3,23,37] Viral antigen in viremic bird blood, infected mosquito pools,

and infected equine brains can be detected directly by antigen capture enzyme-linked immunosorbent assay. Polymerase chain reaction analysis of CSF has been reported but has not been evaluated extensively for routine clinical diagnosis.[52,54]

Serologic testing is available in many state and reference laboratories and is currently the preferred method for diagnosis in patients. Virus-specific IgM usually can be detected in acute serum and CSF samples.[44] Indirect immunofluorescence, neutralization, and hemagglutination inhibition also are sensitive procedures. Antibodies often are present in the first week of illness. Neutralizing antibody appears 3 to 4 days after the onset of illness, and hemagglutination-inhibition (HI) antibody appears with almost equal rapidity.[27] Both HI and neutralizing antibodies appear to be long lived.[27] Complement-fixing (CF) antibody is slower to rise and can be noted 11 days after onset, with diagnostic fourfold rises often appearing only in the third week after onset.[27] The peaks of both HI and CF titers are observed 3 to 4 weeks after onset.[28] CF antibody declines more rapidly. Measurable CF antibodies were found in approximately 50 percent of persons infected 8 years earlier in one study, although the effects of reexposure could not be ruled out in this endemic area.[27]

The low prevalence of EEE antibody in the general population suggests that detection of EEE viral antibody in the acute serum of a patient with encephalitis indicates a high probability of that diagnosis. Applying the Bayes theorem, if the "rate" of EEE is 1 in every 2000 cases of encephalitis, if HI antibody to EEE is present in 100 percent of cases in the first week of illness, and if the prevalence of HI antibody in the general population is 0.05 percent, the presence of EEE in a patient with encephalitis who has demonstrable EEE antibody in a single serum specimen is a certainty.[59] Thus, the probability of the diagnosis is high when specific antibody is found in any (i.e., acute) serum specimen.

DIFFERENTIAL DIAGNOSIS

The fulminant clinical course of EEE, the laboratory findings of neutrophilic leukocytosis and polymorphonuclear pleocytosis in the CSF, and focal findings on brain imaging may suggest bacterial cerebritis or meningitis. Because no specific therapy is available, EEE should be a diagnosis of exclusion after every feasible effort has been made to diagnose and to treat empirically against bacterial and herpes viral infections, as well as exclusion of other herpesvirus and arbovirus infections, influenza virus, enterovirus, rabies virus, and other causes of encephalitis in humans.

TREATMENT

Specific treatment is unavailable. Therapy aimed at supporting cardiorespiratory function, homeostasis of fluid, electrolyte balance, and control of cerebral edema and convulsions may be lifesaving. Antiviral research and development initiatives have focused on agents with activity against EEV, but no specific antiviral agent is licensed for treatment of EEV in humans.[53] In a single case, intravenous immunoglobulin and glucocorticoids, given for their potential immunomodulatory effects, were associated with survival in an elderly patient.[28]

PREVENTION

An effective killed vaccine is licensed for horses, but no human vaccine is licensed. An investigational killed vaccine, available under investigatory permit, is used to protect laboratory personnel.[52] Other vaccine candidates, such as a Sindbis/EEE virus chimeric vaccine and a recombinant EEE virus attenuated by internal ribosomal entry site control, have been tested in vitro and in animal models.[48,60] Vaccination of the general public is not feasible as a public health measure because of the low incidence of disease.

Climatologic studies have shown a correlation between outbreaks and heavy rainfall in the summer of an epidemic year and in the preceding fall.[34,38,40] Although such predictors would have considerable utility in guiding control measures, outbreaks of EEE have been too few for their validity to be tested. Isolation of Highlands J virus, which shares a common enzootic cycle with EEE virus, often peaks 2 to 3 weeks before the appearance of EEE virus in *C. melanura*.

Surveillance and public health interventions to prevent EEE in endemic areas have been shown to be economic when they are balanced against the direct and indirect costs of even one human case.[60] Infection rates in *C. melanura* of 0.39/1000 have been highly predictive of risk for human cases in areas of Massachusetts surveyed during a 26-year interval.[32] Larviciding of swampland to control *C. melanura* is difficult because of the large areas involved, the potential toxic effects in fish and other wildlife, and the relative inaccessibility of the larvae. Emergency application of adulticides to control epizootic vectors is indicated when viral, mosquito, and animal surveillance suggests a risk for epizootic transmission. Public health advisories to avoid outdoor activity near enzootic foci and closure of campgrounds and parks in these locations may be necessary when viral transmission indices suggest a high level of risk. The use of repellents and avoidance of outdoor activity 1 to 2 hours after sunset, when many mosquitoes are most active, may reduce the risk of exposure; however, some vector *Aedes* spp. are daytime biters.

174B ■ WESTERN EQUINE ENCEPHALITIS

Theodore F. Tsai • Gail J. Harrison

Western equine encephalitis (WEE) is an endemic and enzootic acute central nervous system (CNS) infection of humans and horses in the western part of the United States, Canada, Mexico, and parts of South America. In North America, *Culex tarsalis*, the principal mosquito vector, also maintains the virus in an avian enzootic cycle.[77] WEE virus is currently classified as a Biological Safety Level 3 (BSL-3) agent because it is highly infectious and potentially may be transmitted via aerosol and a Category B bioterrorism agent based on its moderate ability to disseminate in the population and produce serious disease in humans.[64]

ETIOLOGIC AGENT

WEE and other alphaviruses (group A arboviruses) form a genus of principally mosquito-borne viruses in the family *Togaviridae*.[47,68] Three of the eight viruses constituting the WEE antigenic complex are found in North America: Highlands J, Fort Morgan, and WEE viruses; among them, only WEE virus is a human pathogen. Much of what is known about the molecular biology of alphaviruses has been inferred from studies of the Sindbis (the type species and a member of the WEE complex) and Semliki Forest viruses.

Alphaviruses are small, enveloped, positive-stranded RNA viruses. Virions are spherical and 69 nm in diameter (including the length of their glycoprotein spikes), with a lipid bilayer enveloping a nucleocapsid core containing the 11.7-kb RNA viral genome.[64] Glycoprotein spikes embedded in the viral envelope bind to cell membrane receptors and initiate infection by endocytotic fusion. The viral and lysosomal membranes fuse in a pH-dependent step, and the viral nucleocapsid is released into the cell cytoplasm, where RNA and protein synthesis occurs. The 5′ terminal two thirds of the RNA genome encodes four nonstructural proteins, and the 3′ terminal third of the RNA genome encodes the three structural proteins. The 30-kd nucleocapsid and two 50-kd glycoproteins—E1 and E2—are translated as a polyprotein from subgenomic 26S RNA. The envelope proteins—E1 and E2—are assembled in trimers of a single E2 protein and an E1 dimer. Eighty such trimer spikes are arranged in an icosahedral lattice on the virion surface.[10] Capsid proteins assemble with the viral genome in the cytoplasm and then bud through the virally modified cell membrane and acquire an envelope.

The E1 glycoprotein possesses a group-reactive hemagglutinin and group-reactive epitopes linked to cross-protection and cell-mediated cytotoxic effects. E1 also mediates viral cellular membrane fusion and has been explored as a vaccine target.[69] Epitopes on E2 are linked to cell receptor recognition, viral neutralization and clearance, and neurovirulence and cellular apoptosis.[73]

Molecular genetic studies indicate that WEE virus arose more than 1000 years ago as a recombinant of eastern equine virus and an ancestral, now extinct, Sindbis-like virus, with the recombinant having acquired the neurotropic potential of eastern equine encephalitis (EEE) virus while retaining the antigenic and nucleocapsid characteristics of the non-neurotropic Sindbis virus.*

Alphaviruses are thought to have originated in the New World with separate introductions, presumably by birds, to the Old World, resulting in establishment of the present-day Sindbis-like viruses and Semliki Forest–related viruses. A slow rate of evolution, circa 10^{-4} nucleotide changes per year (vs. 10^{-2}/year for other RNA viruses), probably reflects the natural pressure on viruses constrained to replicate in both insect and vertebrate cells.[71]

ECOLOGY

WEE virus is transmitted in an enzootic cycle to mosquitoes, birds, and other vertebrate hosts.[50,51,55] Horses and humans are dead-end hosts, but severe CNS infection may develop. Although WEE has been a public health and veterinary problem primarily in the western United States and Canada, the geographic range of the virus includes Mexico, Guyana, Brazil, Uruguay, and Argentina. Epizootics in horses, accompanied by small numbers of human cases, were reported in 1972 and 1983 in Argentina, where the virus apparently is transmitted by *Aedes albifasciatus* to introduced European hares and

possibly birds. In addition, a distinct sylvatic subtype of WEE virus is transmitted in the subtropical Chaco province.[4,7]

In the United States, the geographic distribution of the virus and *C. tarsalis*, its principal vector, includes the western and central United States, southern Canada, and Mexico. A related virus—Highlands J virus, isolated from *Culiseta melanura* in the eastern United States—overlaps in its range in the east central part of the United States. Highlands J virus causes encephalitis in horses and possibly in humans.[38]

In the western region of the United States, *C. tarsalis* breeds in ground pools found on pasture lands; in irrigation wastewater; and at the margins of lakes, ponds, marshes, and flooded riversides. Some of these aquatic habitats are shared by birds that participate in the amplification of virus in nature.[50,51,55]

The female mosquito becomes infected after feeding on a viremic bird (or mammal or possibly reptile). After an extrinsic incubation period of 7 to 9 days, when the virus propagates in the mosquito and the salivary glands become infected, the mosquito can transmit virus to other birds or mammals or reptiles (amplifying hosts) or to humans and horses (dead-end hosts).

Passerine (perching) birds, especially sparrows and finches, have proved to be particularly important in amplification of the virus. In midsummer, the mosquito shifts its host-seeking activity to mammals. The shift may be influenced by an increase in the defensive behavior of nestling birds, which are its preferred host. The shift corresponds temporally to the appearance of cases in horses and people and appears to be a critical element enabling *C. tarsalis* to function as both an enzootic and an epizootic vector. In California, an auxiliary *Aedes melanimon*–jackrabbit *(Lepus californicus)* cycle has been demonstrated.

The overwintering mechanism for WEE virus has not been elucidated. However, virus has been recovered from adult *Aedes dorsalis* mosquitoes collected as larvae from a coastal area of California, thus indicating a possible role for vertical transmission of the virus in mosquitoes in some locations. Arguments also have been advanced for viral overwintering in adult mosquitoes and in persistently infected mammals, birds, and poikilotherms (snakes, frogs, and turtles). Experimental infection of snakes (garter snakes) and tortoises show them to be susceptible to chronic infection with WEE virus.[3] Seroepidemiology studies in the field show high prevalence of WEE virus antibody in reptile hosts, including snakes, lizards, turtles, and crocodiles. Reptiles, because of their low metabolic rate, may function as a reservoir host over the winter and transmit WEE virus to humans via an arthropod vector.[3] In Canada, *Aedes* spp. and *Culiseta inornata*, which emerge in the spring before *C. tarsalis*, have been proposed as early amplifying vectors.[37]

Numerous climatologic and biologic indices with various degrees of predictive value have been shown to correlate with the occurrence of WEE outbreaks; these indices include vector population size, mosquito infection rates, and virus transmission rates to sentinel chickens or wild-caught sparrows. Such transmission indices are monitored in surveillance activities by public health agencies; however, their sensitivity, specificity, and predictive value for forecasting epidemics have been difficult to evaluate because of the sporadic nature of outbreaks.[72] A retrospective analysis of a 21-year experience in California showed correlation between average daily numbers of *C. tarsalis* females and the occurrence of human encephalitis.[44] In a Texas study, house sparrow infection and antibody rates were the best predictors of human disease, and *C. tarsalis* light trap indices were of borderline significance.[27]

Physical measures associated with the incidence of disease in humans or transmission of virus to sentinel species include the ambient air temperature, the snow pack in mountains providing runoff water, the river flow rate, the soil temperature inversion date (the date that the surface soil temperature exceeds the subsurface soil temperature), and the date when 50 or more days of 21°C (70°F) temperature have accumulated. Snow pack and river flow rate are associated with an abundance of irrigation water and flooding, which in turn are associated with the availability of breeding habitats and mosquito population size.[8,26,50,51,52]

Longitudinal and intraseasonal observations show that high temperatures are associated with a reduced risk for human disease. High ambient air temperature (32°F [>89.6°F]) decreases mosquito survival, adversely affects the competence of *C. tarsalis* to become infected with and to transmit WEE virus, and limits host-seeking activity.[56] In a model of global warming, higher temperatures are predicted to move the range of WEE viral transmission northward.[51,52]

EPIDEMIOLOGY

WEE occurs sporadically and in epidemic form, principally in Canadian provinces and states west of the Mississippi River (Figs. 174B-1 and 174B-2). Infections occur mainly in rural areas, where water impoundments, irrigated farmland, and naturally flooded sites

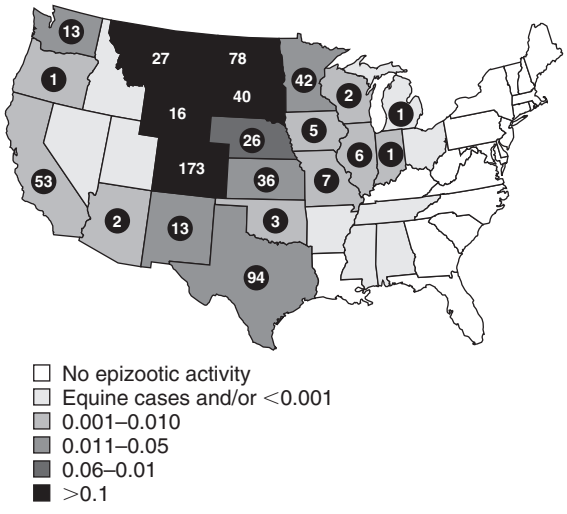

FIGURE 174B-1 ■ Reported cases and average annual incidence (per 100,000) of western equine encephalitis by state, 1964 to 1995.

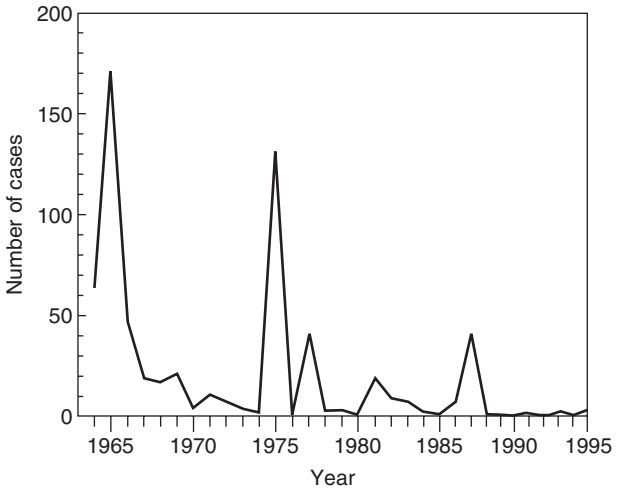

FIGURE 174B-2 ■ Reported cases of western equine encephalitis by year, 1964 to 1995.

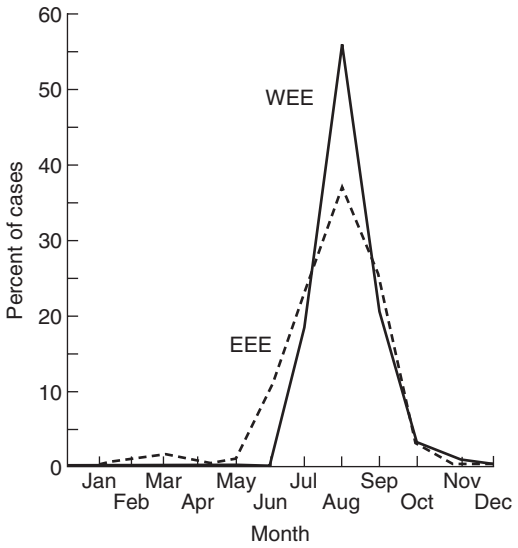

FIGURE 174B-3 ■ Reported cases of western and eastern equine encephalitis by month, 1972 to 1989.

provide breeding habitats for *C. tarsalis;* however, the increasingly rare interface between vector mosquitoes and humans has resulted in a point seroprevalence of 1 to 2 percent even in locations where the virus is transmitted in an enzootic cycle.[56] The annual median number of cases between 1964 and 1995 was only four, and only four cases were reported between 1988 and 1997, a lower incidence than that for EEE. Historically, however, periodic outbreaks have led to scores or hundreds of cases (Fig. 174B-3).

Recurrent endemic and epidemic transmission was recorded in the Yakima Valley, Washington (1939 to 1942); California's Central Valley (1939 to 1952); the north central states and Canadian provinces, including Minnesota, North and South Dakota, Alberta, Manitoba, and Saskatchewan (1941 and 1975); and the high plains panhandle of Texas (1963 to 1966).[15,22,28,49,54] The largest outbreak on record, in 1941, resulted in more than

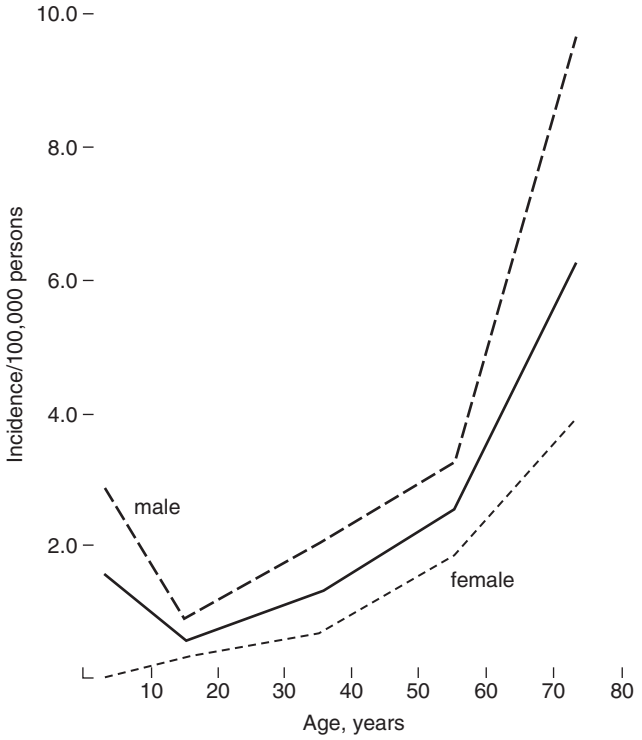

FIGURE 174B-4 ■ Age- and sex-specific incidence of western equine encephalitis, Colorado, 1987. ––, Male; —, total; ---, female.

3400 human cases in Minnesota, North and South Dakota, Nebraska, Montana, Alberta, Manitoba, and Saskatchewan; equine cases were estimated to number in the hundreds of thousands. The outbreak centered in North Dakota, where the attack rate for cases in the state was 167/100,000.[15,32] In 1952, an outbreak in California's Central Valley led to 348 reported cases, an incidence of 36/100,000 residents.[28] More recent outbreaks resulted in 277 cases in the central United States and Manitoba in 1975 and 40 cases in the central and mountain states in 1987.[13,33,37]

Most cases occur between June and September (see Fig. 174B-3), often preceded by cases occurring in horses several weeks earlier. Surveillance of equine cases is a widely used approach to assess the risk for epidemic transmission. However, the low frequency of laboratory-confirmed diagnoses, vaccination, and underreporting limit the precision of equine surveillance as a predictive marker.[46]

Several risk factors for acquiring WEE have been identified:

1. Attack rates usually are highest at the extremes of age[2] (Fig. 174B-4). The experience from the 1952 California outbreak showed that a third of cases occurred in infants younger than 1 year of age.[28,51] Other reports confirm the bimodal pattern of an elevated risk in infants, a declining risk in children and young adults, and a gradual increase in risk in the elderly.
2. Attack rates in males are twofold higher than those in females in every age group[2] (see Fig. 174B-2). Biologic differences in susceptibility to infection

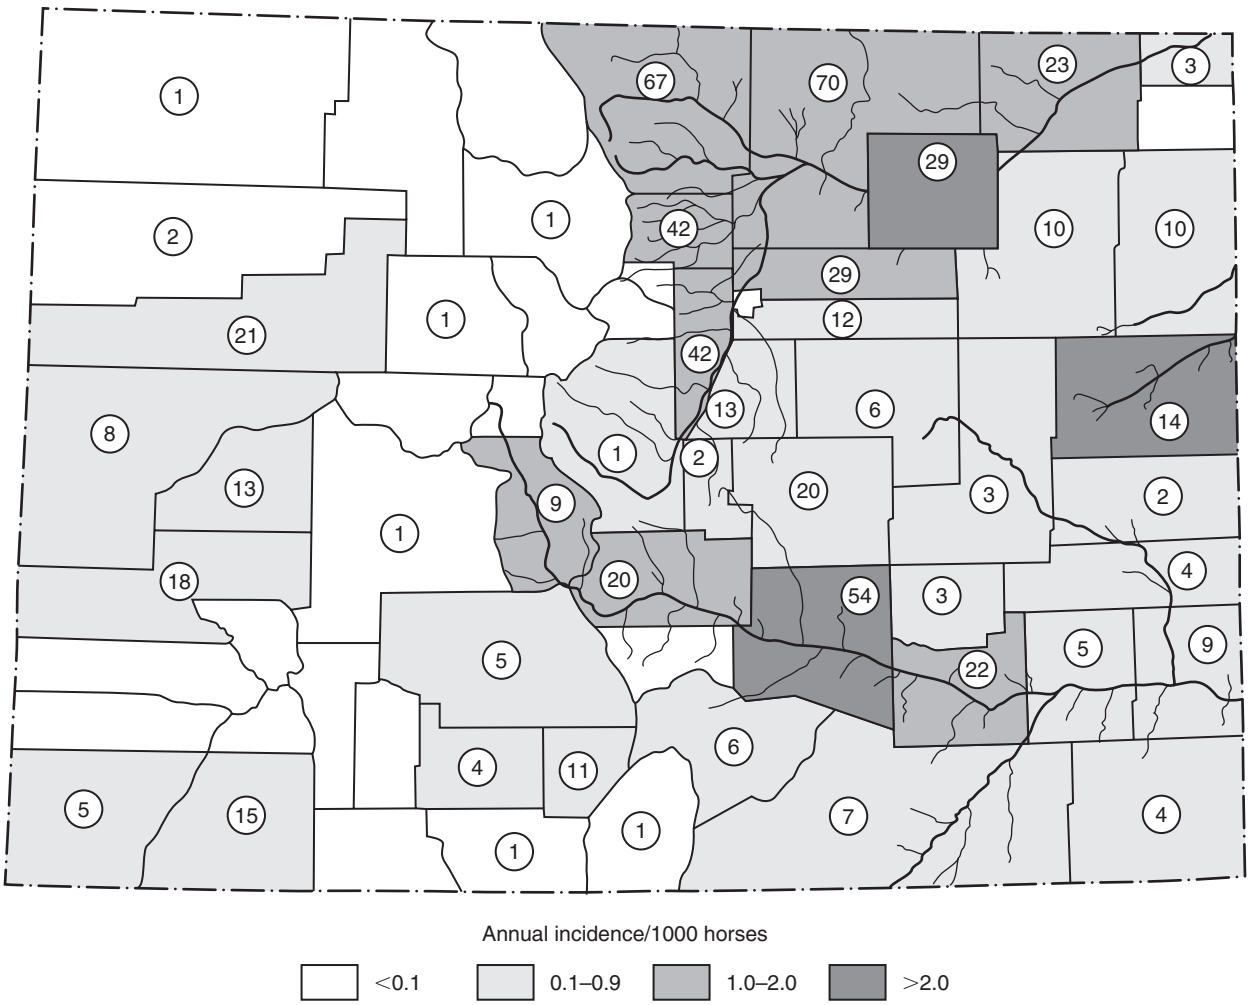

FIGURE 174B-5 ■ Reported equine cases and incidence of western equine encephalitis by county, Colorado, 1975 to 1988.

TABLE 174B-1 **Western Equine Encephalitis Epidemic Attack Rates by Population Density***

Population Area	Minnesota, 1941	Kern County, Calif, 1952	Hale County, Tex, 1963-1966	Manitoba, 1975
Rural	15.8-22.0	149.2	2.62	10.8

Urban		28.5	1.0	0.9

*Per 100,000.

may account for the observed disparity in infancy, and greater occupational and recreational exposure outdoors might be responsible for the differences in adults. In the 1981 outbreak in Manitoba, 21/25 cases were in males; the four affected women were widows who maintained their premises alone.[13]

3. Rural residence is associated with attack rates 1.5 to 5 times higher than those for urban residence (Table 174B-1). Counties lying in major river drainage areas and with more irrigated acreage have had the highest incidence of equine and human disease[2] (Fig. 174B-5).
4. Agricultural occupation has been suggested as a risk factor in several studies.
5. Length of residence in areas where WEE is endemic is associated inversely with a risk for developing illness. Acquired immunity, through asymptomatic or mild infection, accumulates with length of residence; in endemic areas, the point prevalence of specific antibody previously approached 20 percent by adulthood.[50,51]

CLINICAL MANIFESTATIONS

The clinical illness ranges from a nonspecific syndrome of headache and fever to aseptic meningitis, meningoencephalitis, and encephalitis with fatal outcome. The

estimated case-infection ratio is 1:58 in children 1 to 4 years of age, but it declines to 1:1150 in adults.[12,18,51,55]

The onset of illness typically is abrupt, with sudden fever, headache, malaise, chills, and nausea and vomiting,[5,15,25,49] occasionally preceded by signs of an upper respiratory tract infection. Signs of CNS infection gradually become evident as dizziness, drowsiness, increasing headache, stiff neck, and disorientation develop during the course of hours or days. Infants typically have a sudden cessation in feeding, fussiness, fever, and protracted vomiting. The prodromal interval is abbreviated, and seizures and a lethargic unresponsive state develop rapidly.

On examination, patients appear somnolent and may have signs of meningeal irritation. The sensorium is depressed, and patients may alternate between agitation and somnolence. Generalized muscle weakness is present, and deep tendon reflexes are diminished. Focal neurologic signs suggesting herpes encephalitis have been reported in anecdotal cases[1,6] however, in the 1941 Minnesota outbreak, only 3/226 cases reported had unilateral weakness.[15]

In infants, the fontanelle may be tense or bulging, often accompanied by spastic paresis and generalized seizures. The frequency of seizures is related inversely to age; they occur with greatest frequency in infants younger than 3 months (75% to 80% of cases), whereas in 2- to 4-year-old children, seizures have been reported in 15 percent of cases.[36]

The peripheral leukocyte count is unremarkable. Cerebrospinal fluid (CSF) obtained at an early stage in the illness generally exhibits normal glucose concentration, elevated protein level, and a leukocyte count between 10 and 300/mm^4.[33] Mononuclear cells usually predominate.

Five instances of late third-trimester infection in pregnant women have been reported to result in perinatal illness or encephalitis.[11,12,36] The women's illnesses had an onset 0 to 10 days before delivery, and the infants became ill on the fifth and sixth postpartum days. Teratogenic effects of infection occurring earlier in gestation have not been reported for WEE virus but are suspected for other group A arboviruses.[39]

PATHOLOGY

Specific pathologic changes are confined to the CNS.[5,33,42] On gross examination, the brain appears normal or may be congested and swollen, with minimal changes observed in the meninges. Microscopic lesions affecting gray and white matter appear throughout the brain but predominate in the basal ganglia. Disseminated small focal abscesses infiltrated with neutrophils are a distinctive feature. The vessels appear congested, and small focal hemorrhages or diffuse extravasations of erythrocytes are present along with neutrophilic infiltration of the vascular wall and endarteritis. Vascular lumina may be occluded by endothelial proliferation and swelling.

Extensive patchy areas of demyelination are found throughout the brain. Older lesions appear as sharply circumscribed, punched-out plaques. Secondary microglial reaction in demyelinated areas is minimal.

The spinal cord is affected in the same fashion, with focal, perivascular, and diffuse lesions attracting both polymorphonuclear and mononuclear cells. Lesions predominate in the central gray matter.

PATHOGENESIS

Peripheral inoculation of experimental animals with WEE virus is followed by viral replication in various extraneural sites before invasion of the CNS (including the peripheral site of inoculation, viscera, muscle, and perhaps vascular endothelial cells) occurs.[29,34,43,75]

Host resistance and recovery from infection depend chiefly on an effective antibody response. Antibody contributes to recovery by a variety of means, including viral neutralization and antibody-mediated restriction of viral gene expression.[20,73] Interferon may contribute to containment of local viral spread in the CNS. Antibodies are protective and may be cross-protective to other alphaviruses. Antibodies to the E2 glycoprotein typically are virus specific and associated with neutralization and protection. Antibodies to E1 exhibit greater cross-reactivity with other alphaviruses.[68] Immune serum given to monkeys prophylactically protects them from challenge with WEE virus, and passive protection has been demonstrated in monkeys inoculated with WEE virus and treated with immune serum within 24 hours.[75] However, immunotherapy in monkeys is uniformly unsuccessful in preventing death once signs of CNS infection have appeared. In guinea pigs peripherally inoculated with WEE virus, immunotherapy given within 24 to 48 hours of inoculation leads to survival of some animals and delayed death in others.[43] In one human case, passive immunization led to a delayed antibody response and was followed by the development of parkinsonism.[19]

The age-dependent virulence of specific Sindbis virus strains has been linked to the immaturity of the suckling mouse T- and B-cell repertoire. Fibroblasts from newborn but not weanling mice are susceptible to Sindbis virus infection, and viral infection of immature mouse neurons leads to apoptotic cell death. Mature neurons are protected against apoptosis by induction of the *bcl-2* oncogene, whose products convert the infection to a persistent nonlytic infection. Viral persistence in the brain of recovered mice is modulated by antibody.[20]

PROGNOSIS

Major neurologic sequelae of WEE, including quadriplegia, hemiplegia, spasticity, intracerebral calcifications, developmental delay in children, and epilepsy, have been reported in approximately 13 percent of cases.[14,16,25,78] The risk for development of serious neurologic sequelae in infants is triple that of other age groups, and 30 percent of recovered infants younger than 1 year remain seriously impaired.[16,18,67] In infants younger than 1 year, seizures during the acute phase of illness were associated with a

greater risk for poor long-term outcome, including continued seizures. Multiple intracranial calcifications were observed in one recovered infant with persistent seizures.[66] Minor psychiatric or neurologic deficits remained in approximately one fourth of children and adults monitored for 18 months after infection.[16] Central apnea has been reported as a complication of encephalitis in two adult cases.[74]

Parkinson syndrome has been a residual effect in at least 15 cases of adults surviving WEE.[19,41,62,63]

Its onset may be immediate or delayed for several years after recovery from the illness. Two retrospective investigations of patients with idiopathic Parkinson disease found no difference between cases and controls in seroprevalence to several arboviruses, including WEE virus.

The case-fatality rate in reported cases in the United States from 1955 to 1978 was 3 to 4 percent. In outbreaks in the central portion of the United States and Canada in 1941, 1975, and 1981, approximately 7 to 9 percent of patients died, with higher fatality rates in the elderly.

DIAGNOSIS

Virus rarely can be recovered from blood or CSF, but it can be isolated readily from the brain of fatal patients. In a few attempts, WEE virus has been isolated from brain biopsy material; in principle, rapid diagnosis can be made by immunofluorescent identification of WEE viral antigen in brain biopsy tissue. The virus can be isolated readily, under BSL-3 containment precautions, in Vero cell culture or in suckling mice.[63] Nucleic acid–based sequence amplification and real-time reverse-transcriptase polymerase chain reaction (RT-PCR) assays of CSF appear to be sensitive and specific. Duplex real-time RT PCR assays that not only detect but also discern between alphaviruses have recently been developed.[30]

Immunoglobulin (Ig)M capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic procedure and is available from public health laboratories and commercial reference laboratories.[35] IgM antibody usually is present in acute serum within a week after the onset of illness, and its presence is presumptive evidence of recent infection. IgM often can be detected in CSF before it can be identified in serum, and its presence, which indicates intrathecal production of antibody, confirms a recent CNS infection.[35] Identification of virus-specific IgM in serum and CSF by immunofluorescence also is possible; however, this approach is somewhat less sensitive than IgM capture ELISA and may be confounded by the effects of rheumatoid factor.

Hemagglutination-inhibition and neutralizing antibodies are elevated in the first week of illness in most cases, and a diagnostic fourfold rise in titer usually is observed in the second week. Complement-fixing antibody is slower to rise, with fourfold changes delayed until the third to fifth week after onset. The complement-fixation response may be blunted in older patients.[67]

Neutralizing and hemagglutination-inhibition antibody titers have considerable longevity, with minimal decay noted 30 months after onset. In contrast, complement-fixing antibody is relatively short-lived, and its presence is a useful indicator of recent infection, particularly in endemic areas where long-term residents may have neutralizing and hemagglutination-inhibition antibody from previous exposure. Only two thirds of patients are estimated to show complement-fixing antibody 2 years after onset, and fewer than 15 percent have residual complement-fixing antibody after 5 years.[67]

DIFFERENTIAL DIAGNOSIS

The clinical findings in patients with encephalitis seldom are sufficiently characteristic that a specific diagnosis can be made on clinical grounds alone. Fever, vomiting, signs of meningeal irritation, and confusion are nonspecific features of encephalitis and cerebral edema. Early symptoms in infants, such as fever, lethargy, and vomiting, may be even less specific.[31]

Furthermore, the peak occurrence of arboviral infection in midsummer to late summer temporally overlaps the seasonal occurrence of other CNS infections by enteroviruses (e.g., echovirus 13, which recently has become epidemic in the United States), leptospires, free-living amebae, and mosquito-borne West Nile and St. Louis encephalitis.[54] CNS signs may be prominent in other summertime diseases, such as Rocky Mountain spotted fever, heat stroke, shigellosis, and lead encephalopathy. High priority should be given to establishing a specific diagnosis of treatable conditions, such as herpes simplex virus and enteroviral infection, while bearing in mind that dual arboviral and enteroviral infection has been reported.[6]

Other causes of CNS infection without an established summertime seasonality that also should be considered in the differential diagnosis include fungal, mycobacterial, and partially treated bacterial meningitis; brain abscess and infected subdural collections; bacterial endocarditis; toxoplasmosis; cat-scratch disease; and infections with rabies virus, mumps virus, herpes simplex virus, Epstein-Barr virus, human herpesvirus 6, adenovirus, lymphocytic choriomeningitis virus, and human immunodeficiency virus. Parainfectious disorders such as postinfectious viral encephalitis, acute cerebellar ataxia of childhood, mycoplasmal infection, neuroblastoma with opsoclonus, and Reye syndrome also may enter into the differential diagnosis. Vascular disorders formed the largest single group of disorders mimicking herpes encephalitis in several studies. Drugs (e.g., trimethoprim-sulfamethoxazole, penicillin, isoniazid, phenazopyridine, ibuprofen, tolmetin, sulindac, and carbamazepine), high doses of bismuth, OKT3 antibody, and vidarabine also may cause aseptic meningitis or encephalopathy.

Because of the potential for their overlapping circumstances of exposure, diethyltoluamide (DEET) encephalopathy should be excluded. DEET-containing insect repellents have been implicated as a cause of seizures and encephalopathy after brief cutaneous exposure (see later discussion).

Valuable clues to the diagnosis of an arbovirus infection are gleaned from a history of travel, residence, or occupational and recreational activities within the appropriate incubation period. Suspected cases should be reported to public health officials.

TREATMENT

Specific U.S. Food and Drug Administration–approved antiviral therapy is not available for WEE. However, novel small molecule inhibitors of neurotropic alphaviruses, including WEE virus, are in preclinical development.[45,53,65] Supportive treatment of acutely ill patients includes monitoring of cardiorespiratory function, fluid and electrolyte balance, and intracranial pressure. A case of laboratory infection treated with immune equine serum resulted in recovery; however, acute Parkinson syndrome developed in this patient and coincided temporally with serum sickness resulting from immunotherapy.[19]

PREVENTION

Killed vaccine prepared in chick embryo fibroblast culture is available in the United States under an investigatory permit for laboratory and field personnel who are at risk for occupational exposure. Effective killed vaccines are available for horses and usually are administered in bivalent or multivalent formulations (i.e., with EEE, Venezuelan equine encephalitis, and influenza viruses). Potential vaccine targets for WEE are under investigation, and include E1 envelope protein targets and adenovirus vectored vaccines.[69,76] Vaccination of the general public, even in endemic areas, is not a practical consideration because of the low risk for disease.

Personal protective measures are encouraged when travel or living in endemic areas, and include avoidance of outdoor activity during the hours of peak mosquito activity at dusk and use of repellents.

The Centers for Disease Control and Prevention (CDC) recommends repellents containing DEET or picaridin (KBR3023) as active ingredients.[8,9,17,23,48] DEET is absorbed readily through the skin, and its absorption and absorption of oxybenzone, a common sunscreen preparation, are increased when they are used in combination. Some authorities recommend that sunscreens be applied first and more liberally, followed by insect repellent applied sparingly because of concerns about the potential neurotoxicity of DEET.[8,58,59] Three cases were fatal. In one recovered child, encephalopathy and seizures developed after only two applications. In an additional child, seizures and encephalopathy occurred after the child had cutaneous and respiratory exposure to DEET in an automobile with closed windows. Additional cases of seizures in patients who used small quantities of DEET have been reported, but whether these events were coincidental in populations in which the prevalence of DEET use is high is unclear.[9] DEET may have an effect on ammonia metabolism; in one case, encephalopathy occurred in a patient with partial ornithine carbamoyltransferase deficiency.[24] DEET is a proved neurotoxin when it is ingested; however, the incidence of neurologic side effects after cutaneous exposure is unknown. Nonetheless, avoiding formulations containing DEET in high concentration is prudent; when it is applied simultaneously with sunscreen, DEET repellency is unhampered but ultraviolet protection may be reduced. Precautions for the prudent use of repellents as recommended by the CDC and U.S. Environmental Protection Agency (EPA) are listed in Table 174B-2.

TABLE 174B-2 Precautions to Reduce Potential Adverse Reactions from Repellents

DEET is approved for use on children older than 2 months. Read and follow label instructions.
Repellents should be applied only to exposed skin and clothing (as directed on the product label). Do not use under clothing.
Never use repellents over cuts, wounds, or irritated skin.
Avoid mucosal contact—do not apply to the eyes and mouth, and apply sparingly around the ears. When using sprays, do not spray directly onto the face; spray on the hands first and then apply to the face.
Do not allow children to handle the product, and do not apply to children's hands. When using on children, apply to your own hands and then put it on the child.
Do not spray in enclosed areas. Avoid breathing a repellent spray.
Avoid ingestion, and do not use the product near food.
Use just enough repellent to cover exposed skin and clothing.
Heavy application and saturation are unnecessary for effectiveness; if biting insects do not respond to a thin film of repellent, apply a bit more.
After returning indoors, wash treated skin with soap and water or bathe. This precaution is particularly important when repellents are used repeatedly in a day or on consecutive days. Also, wash treated clothing before wearing it again.
Pregnant and nursing women should minimize the use of repellents.
If you suspect that you or your child is reacting to an insect repellent, discontinue use, wash treated skin, and then call your local poison control center. If you go to a physician, take the repellent with you.
Specific medical information about the active ingredients in repellents and other pesticides is available at the National Pesticide Information Center at 1-800-858-7378.

Modified from U.S. Environmental Protection Agency recommendations. Available at http://www.epa.gov/pesticides/factsheets/chemicals/deet/htm.

Repellents containing oil of lemon eucalyptus (but not "pure" oil of lemon eucalyptus) and registered with the EPA as repellents also may provide a similar level of protection.

Permethrin, a synthetic pyrethroid available as a 0.5 percent aerosol (Permanone), is both insecticidal and a repellent.[9,17,61] Permethrin is extremely effective in reducing the incidence of mosquito and tick bites when sprayed on clothing and shoes, and it also can be applied to tents, mosquito nets, and other gear.[17,60] Its use on the skin is not approved, except as treatment of scabies and head lice.

Prevention is focused primarily on interruption of the transmission of virus from mosquitoes to humans. In

many localities where WEE is endemic, mosquito abatement districts monitor mosquito populations, virus infection rates in the vector population, or evidence of transmission of virus to wild or sentinel birds and chickens to provide a basis for predicting epidemic transmission and for emergency mosquito control.[40,57]

As a general rule, *C. tarsalis* densities exceeding 10 to 15 females per trap night and mosquito infection rates greater than 5 to 10/1000 signal a risk for epizootic transmission. Evidence of seroconversion in sentinel chickens and observations of equine cases are further indications that human cases may occur.

174C ■ VENEZUELAN EQUINE ENCEPHALITIS

Theodore F. Tsai • Gail J. Harrison

Mosquito-borne Venezuelan equine encephalitis (VEE) arguably is the most important viral zoonosis in Latin America. The disease, known locally as *peste loca*, has occurred in combined epizootics and epidemics at regular intervals since the 1920s, sometimes leading to hundreds of thousands of human and equine cases. Between 1935 and 1961, 11 outbreaks were reported, and from 1962 to 1973, epizootics recurred in every year except 1965.[1,4,19,42] The virus was isolated from horse brain in 1938 during an outbreak in Venezuela. Although outbreaks have arisen principally in northern South America, especially from Colombia and Venezuela, in a remarkable period between 1969 and 1971, epizootics and epidemics were reported from Colombia, Venezuela, Ecuador, Peru, all the countries of Central America (except Panama), Mexico, and the state of Texas.[1,4,14,29,42] Subsequently, no major epizootics or epidemics were recognized until a large outbreak emerged in Venezuela and Colombia in 1995.[7,8,34,46] Molecular phylogenetic analyses performed in the wake of that outbreak suggested that epizootic strains arise spontaneously from sylvatic viral strains circulating silently in nature.[3,6,24,46] VEE virus is classified as a Category B bioterrorism agent and a Biosafety Level 3 (BSL-3) agent, based on its ability to cause disease in humans, ease of production and stability, and potential for aerosol dissemination in the population.[49]

ETIOLOGIC AGENT

VEE virus is antigenically distinct from other alphaviruses in the Togaviridae family, but is a complex of antigenically and ecologically distinct viral subtypes (Table 174C-1).[32,38,44,45,48] Epizootic subtypes IAB and IC are so named because they have been associated with major outbreaks in horses. Sylvatic viral subtypes circulate in silent cycles of rodent- or bird-mosquito transmission and in general do not cause encephalitis in equines. Both epizootic and sylvatic viral strains cause human illness. VEE virus is an enveloped virus with a nonsegmented, positive-sense RNA genome of approximately 11 kb in length.

VEE virus is thought to have evolved approximately 1400 years ago from a now extinct ancestral alphavirus in one of two extant lineages of New World alphaviruses represented by eastern equine encephalomyelitis and VEE viruses.[32] Because epizootic VEE viral strains had never been isolated from nature except during epizootics, their reservoirs and the mechanisms by which they emerge to cause outbreaks had remained a puzzle. However, recent molecular phylogenetic analyses have found a close genetic relationship between the epizootic IC and the sylvatic ID strains, thus suggesting that these epizootic strains might arise spontaneously by mutation from naturally circulating ID virus.[1,3,6,45] Other outbreaks have had an iatrogenic source from improperly inactivated equine vaccine.*

Comparisons of the attenuated TC-83 vaccine strain of VEE virus and the epizootic IAB parent virus and mutations of virulent infectious clones have shown that changes associated with attenuation occur principally in

TABLE 174C-1 **Viruses in the Venezuelan Equine Encephalomyelitis Complex**

Subtype	Variety	Pattern of Transmission	Location	Transmission Cycle
I	AB	Epizootic	South, Central, and North America	Various mosquitoes and biting insects: equines
	C	Epizootic	Northern South America	Various mosquitoes and biting insects: equines
	D	Enzootic	Ecuador, Panama, Colombia, and Venezuela	*Culex (Melanoconion) ocossa* and *panocossa:* rodents, aquatic birds
	E	Enzootic	Central America	*Culex (Melanoconion) taeniopus:* rodents
	F	Enzootic	Brazil	Unknown
II (Everglades)		Enzootic	Southern Florida	*Culex (Melanoconion) cedecei:* rodents
III	A			
	Mucambo	Enzootic	South America	*Culex (Melanoconion) portesi:* rodents
	B			
	Tonate	Enzootic	South America	Unknown
	Bijou Bridge	Unknown	Western North America	*Oeciacus vicarius:* birds
	C	Enzootic	Peru	Unknown
	D	Enzootic	Peru	*Culex (Melanoconion): Proechimys* spp.
IV (Pixuna)		Enzootic	Brazil	Unknown
V (Cabassou)		Enzootic	French Guiana	Unknown
VI		Enzootic	Argentina	Unknown

genes encoding the E2 and E1 glycoproteins but also in the 5′ nontranslated region.[3,6,20,38] Attenuation is associated with reduced neuroinvasiveness (i.e., faster clearance from blood and lower viremia levels) and reduced neurovirulence (i.e., minimal histopathologic changes after intracerebral inoculation of horses).

VEE virus rapidly produces cytopathic effects in a variety of cell cultures, including Vero, LLC-MK2, and BHK-21 and in primary chicken and duck embryo cells. Epizootic strains cause lethal infections in horses, donkeys, mules, rabbits, and dogs. In certain guinea pig strains, pathogenicity is correlated with equine virulence.

EPIDEMIOLOGY AND ECOLOGY

Epizootics and concurrent epidemics of VEE caused by the IAB and IC strains typically have led to thousands and, on at least one occasion, hundreds of thousands of cases in humans and equines. Most such outbreaks have occurred in Venezuela and Colombia and have been caused by IC viruses (see earlier discussion) (Fig. 174C-1).[34,37,45,46] The circumstances leading to the emergence of outbreaks are poorly understood, but outbreaks often have occurred in arid areas during years of heavy rainfall and flooding, especially during the dry season.[42] The importance of a nonimmune horse population to amplify the virus was underscored in the most recent outbreak in 1995, which occurred in areas of Colombia and Venezuela where equine immunizations had lapsed.[7,34,46] Equines are the most important vertebrate amplifying host because high levels of viremia develop and are sustained in equines, and they provide a large surface area

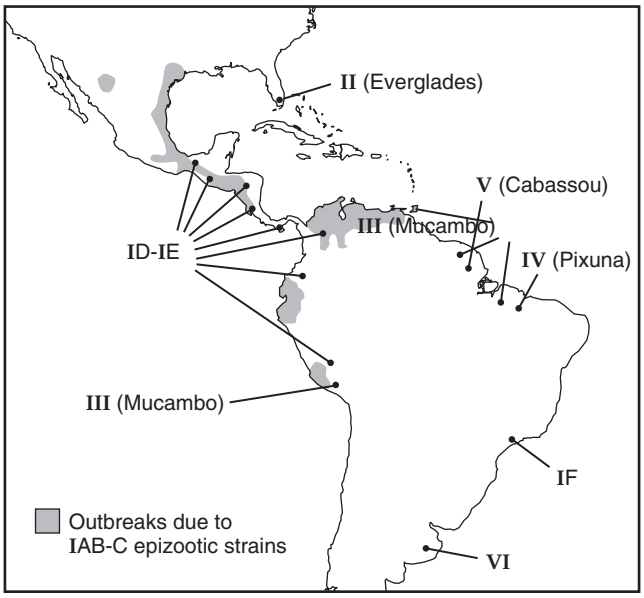

FIGURE 174C-1 ■ Locations of Venezuelan equine encephalitis (VEE) outbreaks caused by type IAB-IC epizootic strains and locations where VEE sylvatic subtypes have been recognized.

for biting mosquitoes. Numerous species of mosquitoes and other blood-feeding insects, among them *Aedes taeniorhynchus*, a salt marsh mosquito, and *Psorophora confinnis*, found in ground pools, can transmit the virus from horse to horse and from horse to human.[40]

Infections are transmitted rapidly among animals and to people such that outbreaks can disseminate at rates of several miles per day. The epidemic curve of human cases usually follows the equine epizootic by several weeks, and

epidemic transmission ceases when the number of susceptible horses has been exhausted by immunization or natural infection.[16,42]

The role of other animals, including humans, in sustaining epidemic viral transmission has been investigated in urban outbreaks, during which household clustering of cases has been observed, and in recent outbreaks, during which few horses were kept in the community. VEE virus levels in human blood are sufficiently high to infect mosquitoes, and virus also has been isolated from the pharynx of ill persons, indicating the possibility of person-to-person transmission by mosquitoes such as *Aedes aegypti* or by direct close contact.[3,39] Although such transmission mechanisms may account for some cases, a household survey found that rates of apparent secondary transmission were no higher than the underlying community attack rate.[7,34] Community attack rates of 20 to 50 percent have been recorded, and the brief course of epidemics in intervals as short as 1 month underscores the considerable force of epidemic transmission.

The series of epizootics beginning in Guatemala in 1969 and reaching Texas in 1971 was caused by an IAB virus that is almost genetically identical to the 1943 Trinidad donkey (epizootic IAB) virus used in inactivated vaccines, thus leading to the conclusion that these outbreaks were iatrogenic and caused by the use of inadequately inactivated equine vaccine.[4,21,45] Another outbreak in Argentina was traced to a similar cause. Serologic serosurveillance in the Gulf Coast region of Mexico conducted between 2003 and 2010 showed the Gulf Coast lineage of VEEV continues to actively circulate and be responsible for infection of animals and humans in this region.[34]

In contrast to the epizootic strains, sylvatic VEE viruses are avirulent in horses and cause a low level of viremia after infection, subclinical or mild illness, and minimal inflammatory change after direct intracerebral inoculation.[43] However, outbreaks of enzootic IE-like viruses rarely have caused outbreaks and deaths in horses (e.g., in Chiapas, Mexico, in 1993). The viruses are maintained in mosquitoes, principally *Culex (Melanoconion) taeniopus* in marshy coastal lowlands, in rodents, and in aquatic birds. In coastal lagoons in Panama, ibises *(Endocinus albus)* and spoon-billed ducks *(Cochlearius cochlearius)* appear to serve as intermediate hosts.[2] VEE subtype II virus, the Everglades virus, is enzootic among cotton rats and other small mammals in the Everglades swamp and probably over a much larger area of Florida but rarely has caused human illness.[9,12] The other VEE virus found in the United States, Bijou Bridge virus, is a nonpathogenic virus thought to have evolved from South American subtype III virus transferred as recently as 40 years ago, probably by a migrating bird.

VEE infections caused by sylvatic strains can be considered "diseases of place" that occur sporadically in persons who enter sylvatic habitats where the viruses are maintained.[2,9] Sporadic cases and rare outbreaks among soldiers in field bivouacs have been reported, but seroprevalence rates in local populations range as high as 75 percent in some locations (e.g., Chiapas, Mexico).[17,36] Many infections are undoubtedly undiagnosed. Bridge vectors, mosquitoes that feed on mammals in the enzootic transmission cycle and subsequently on humans, usually are responsible for these infections.

Numerous cases and outbreaks of VEE have occurred in laboratories when infective aerosols were generated in laboratory procedures.[22] It also has been developed as a biological weapon in the United States and the former Soviet Union.[49] Laboratory manipulations should be undertaken only in BL-3 laboratories and by immunized personnel.

Travelers to Central or South America may return to nonendemic areas with signs and symptoms of VEE. Careful travel history is therefore important in patients who seek medical care with signs and symptoms of encephalitis.[26]

CLINICAL MANIFESTATIONS

The incubation period is brief—2 to 5 days—and in many accounts, the onset of illness was so sudden that it was timed to an exact hour.[22] Fever, chills, headache, myalgia, and malaise are the earliest symptoms, and illness quickly leads to prostration. Photophobia, neck stiffness, backache, conjunctivitis, and sore throat are also common symptoms that occur in approximately one quarter or more of cases. Gastrointestinal complaints, especially nausea and vomiting, and, to a lesser degree, loose stools or diarrhea, are reported frequently.[5]

Physical examination discloses severe prostration and few specific findings. The face may appear hyperemic; inflammation of the pharynx is common; and, occasionally, tonsillitis, palatal ulcers, or petechiae are observed. The cervical lymph nodes may be enlarged and tender. Conjunctivitis and conjunctival suffusion are noted frequently. Nuchal rigidity can be elicited in 10 percent of cases, more often in children. Despite the disease's name, confusion, agitation, and mild disturbances in consciousness suggesting encephalitis are present in only 5 to 10 percent of cases, and patients with significant neurologic findings, such as cranial nerve palsy, motor weakness and paralysis, seizures, and coma, usually account for fewer than 5 percent of all cases.[5,34,35] In epidemics, neurologic findings and encephalitis occurred more commonly in children; however, sporadic cases, including encephalitis caused by VEE subtype II (Everglades) and III (Tonate) viruses, have occurred in middle-aged or elderly adults.[12,17] The fatality rate among patients with encephalitis is 10 to 25 percent, or about 0.5 percent of all cases.[34,35]

In many patients, the illness has an apparently biphasic course; seizures, projectile vomiting, and ataxia occur several days after the onset of fever, followed rapidly by a complete resolution of symptoms. Sequelae such as nervousness, forgetfulness, recurrent headache, and easy fatigability are common occurrences and may persist for months or even up to 1 year. Motor abnormalities usually resolve without residual deficit; however, rarely, sensory and motor abnormalities may persist. Long-term effects on psychometric examination have been reported.[23]

Experimental observations in animals suggest that congenital infection may lead to central nervous system (CNS) anomalies such as porencephaly, micrencephaly,

and hydrocephalus.[24] A similar pattern of structural brain abnormalities has been observed in virus culture–positive fetuses aborted during outbreaks.[46,47] Pancreatic β-cell infection occurs in experimentally infected animals and has led to speculation that VEE may be followed by diabetes, but epidemiologic studies have failed to find an association.[23]

The principal clinical laboratory finding is leukopenia (<4500/mm^3), the nadir of which occurs on the fourth day of illness.[5,11] After the onset of illness, the absolute neutrophil count declines from normal values to 500 to 2000; total lymphocytes are depressed at the onset of illness and gradually recover after 1 week. The platelet count may be diminished below 100,000 mm^3, and lactate dehydrogenase and hepatic transaminases may be elevated moderately. Cerebrospinal fluid (CSF) shows a lymphocytic pleocytosis of up to several hundred cells, moderately elevated protein level, and normal or slightly depressed glucose concentration.

PATHOLOGY AND PATHOGENESIS

VEE virus is both lymphotropic and neurotropic.[10,41] Pathologic changes are observed consistently in the lymph nodes, spleen, lungs, liver, gastrointestinal lymphoid tissue, and brain, with inflammatory infiltrates of mononuclear and polymorphonuclear cells. The lymph nodes and spleen show pronounced lymphoid depletion and necrosis of the germinal centers, along with neutrophilic infiltration and lymphophagocytosis. The selective depletion of lymphoid follicles, with sparing of the paracortical areas and the thymus, suggests that VEE virus principally destroys B cells. These histopathologic changes are reflected in the early lymphopenia seen in the peripheral blood. The liver shows patchy hepatocellular degeneration typical of viral hepatitis. A diffuse interstitial pneumonia with a mixed intraseptal inflammatory cell infiltrate is a consistent finding, and some cases also exhibit intra-alveolar hemorrhage, secondary bronchopneumonia, or both. The brain shows only congestion and edema in most cases. Mild, often focal meningitis and changes associated with encephalitis, perivascular inflammatory infiltrates, and neuronal degeneration are found in a large number of cases.[10] The consistent presence of congestion and edema in various organs and the necrotizing vasculitis seen in some cases suggest that vascular endothelial cells may be a target of infection. This speculation is supported by the observation of VEE viral antigen in the vascular endothelial cells of experimentally infected animals. Secondary immune-mediated destruction of infected vascular endothelia and lymphoid cells may account for delayed clinical manifestations.

LABORATORY DIAGNOSIS

VEE virus can be recovered and grown in cell culture from blood during the first 3 days of illness in at least 75 percent of cases, although isolates have been made after 6 days.[3,4] Virus also has been recovered from throat swabs in approximately 25 percent of cases.[23] Specimens should be inoculated onto Vero or other susceptible cell cultures, but only in a laboratory with BL-3 level containment because of the risk for laboratory aerosol-associated infection. Virus in samples collected and transported in commercial transport media may not support the growth of VEE, but will preserve the nucleic acid and protein integrity of the virus.[18] As an alternative to viral isolation, genomic sequences in acute viremic blood and other samples can be detected rapidly and with high sensitivity by polymerase chain reaction in reference laboratories, and genotyped using reverse-transcription nested PCR assay.[30] Establishing the subtype of VEE viral isolates is vital because subtypes IAB and IC have a potential for epidemic spread. Isolates can be identified rapidly with subtype-specific monoclonal antibodies.

Immunoglobulin (Ig)M capture enzyme-linked immunosorbent assay is the recommended serologic procedure. Both serum and CSF specimens can be tested by this means. Elevated virus-specific IgM in a single serum or CSF specimen is diagnostic and often obviates the need for a second paired serum. An epitope-blocking assay can differentiate antibody responses among serotypes.[44]

DIFFERENTIAL DIAGNOSIS

The self-limited acute febrile illness that characterizes most VEE cases resembles infection caused by dengue, Oropouche, Mayaro, group C bunyaviruses, and various other arboviruses. The epidemic occurrence of cases may suggest dengue or Oropouche fever; however, the absence of rash and hemorrhagic manifestations and an association with equine deaths strongly indicate VEE until it is disproved. Eastern and western equine encephalitis overlap with VEE in some areas of Latin America, but only sporadic human cases have been recognized. Clinical recognition of sporadic VEE caused by sylvatic viruses is difficult; the diagnosis should be entertained in patients with CNS infection and an appropriate exposure history.

TREATMENT

No specific U.S. Food and Drug Administration approved antiviral treatment is available for VEE. Symptomatic treatment with antipyretics and fluids alone is sufficient in most cases. In patients with encephalitis, anticonvulsants may be needed, and intensive supportive care, especially early recognition and treatment of secondary pneumonia, may improve the outcome. Combinations of short interfering RNAs and passive immunization with humanized monoclonal antibodies are under preclinical development and investigation as therapeutic interventions.[15,27,33]

PREVENTION

Immunization with experimental live attenuated TC-83 vaccine is indicated for laboratory and field personnel with a high risk for exposure to VEE virus.[31] However,

the vaccine is immunogenic in only 85 percent of vaccinees, and significant side effects consisting of fever, stiff neck, malaise, and myalgia develop in approximately 20 percent of vaccinees.[13] Previous vaccination with alphaviral vaccines may interfere with response to TC-83, but after immunization with experimental inactivated TC-84 vaccine, antibody will develop in approximately 75 percent of persons who failed to respond to TC-83.[13,25] Safer candidate vaccines that may provide better protection against respiratory infection are being investigated.

Immunization of equines with TC-83 vaccine is the best approach to preventing the emergence of outbreaks. Inadequately inactivated vaccine prepared from epizootic IAB strains poses a danger of producing iatrogenic outbreaks and should be used only if appropriate safety and quality assurance standards of vaccine production have been met. The original TC-83 vaccine virus also may be transmitted by mosquito vectors, efforts to improve its safety by preventing its ability to infect insects were done, through manipulation of structural protein gene expression to produce further attenuation and render it incapable of replicating in insects.[28] Because the live vaccine provides rapid immunity after a single dose, it is the most effective approach in combating outbreaks. Attenuated vaccine is available commercially in certain Latin American countries, but in the United States, only inactivated vaccine formulated with western and eastern equine encephalitis and equine influenza and tetanus antigens is licensed. An improved candidate vaccine, V3526, has been shown to be efficacious in horses.[13] Preclinical development of new, novel VEE vaccines includes Sindbis virus and VEE chimeric viruses, alphavirus replicon particles, DNA vaccines, and adenovirus vector vaccines.[28]

Mosquito control with a combination of larvicides and adulticides may be indicated to mitigate large outbreaks. Taking precautions against mosquito bites, such as using repellents, staying in well-screened or air-conditioned areas when possible, and wearing long-sleeved shirts and long pants, is advised for persons who cannot avoid traveling to areas experiencing epidemics.

174D ■ CHIKUNGUNYA

Scott B. Halstead

Chikungunya is a benign, dengue-like syndrome characterized in adults by the abrupt onset of fever, arthralgia, maculopapular rash, and leukopenia. The term in Makonde means "that which bends up" and refers to the characteristic symptom of arthralgia.[67] In historical times, the terms *knokkel koorts*, *abu rokab*, *mal de genoux*, *dengue*, *dyenga*, and *3-day fever* have been given to epidemics probably caused by chikungunya virus.[12]

The classic account, widely cited as being the initial description of epidemic dengue fever, is that of David Bylon, who was *staads chirurgyn* ("city surgeon") to the city of Batavia (Jakarta) in the year 1779.[9] Dr. Bylon, who himself contracted the illness, wrote the following:

> *It was last May 25, in the afternoon at 5:00 when I noted while talking with two good friends of mine, a growing pain in my right hand, and the joints of the lower arm, which step by step proceeded upward to the shoulder and then continued onto all my limbs; so much so that at 9:00 that same evening I was already in my bed with a high fever. …*
>
> *It's now been three weeks since I … was stricken by the illness, and because of that had to stay home for 5 days; but even until today I have continuously pain and stiffness in the joints of both feet, with swelling of both ankles; so much so, that when I get up in the morning, or have sat up for a while and start to move again, I can not do so very well and going up and down stairs is very painful.*

This account of a febrile illness of acute onset with involvement of the joints clearly suggests that the disease was chikungunya (see discussion of clinical manifestations).

In the same year in Cairo and Alexandria, Egypt, another outbreak of disease occurred that bears a close resemblance to chikungunya.[12,72]

An important pandemic of "dengue" occurred in the years 1870 to 1873; it appeared first on the East African coast and then on the Arabian coast and in Port Said,

Egypt. From there, it was carried to Bombay and Calcutta, India, and Java. The 1870 outbreak led to the recognition that the Swahili words for this disease were *ki-dinga pepo*.[18] The term *denga* or *dyenga* had been used to designate the disease in Africa in an earlier outbreak in 1823. In this pandemic, dengue had spread with the slave trade to the Caribbean, where in 1827 and 1828 an extensive outbreak occurred in the West Indies. In Cuba, the Spanish homonym "dengue" was used first. Written or serologic evidence exists of chikungunya pandemics in India in 1824 and 1825, 1871 and 1872, 1923, 1964 to 1965, and 2006.[12,40]

In 2005 to 2006 a notable epidemic occurred on Reunion, Mauritius, Madagascar, Mayotte, and Seychelles.[65] This soon spread to India and to Southeast Asia.[40,63] The Reunion outbreak was notable because *Aedes albopictus* was the vector.[5,225] This virus was brought by tourists to Europe, with modest autochthonous outbreaks occurring in southeastern France and northeastern Italy.[26,61]

Chikungunya virus was isolated first by inoculation of suckling mice from an explosive dengue-like epidemic in the Makonde district on the border between Tanganyika and Mozambique in 1952.[43,51,67,68]

ETIOLOGIC AGENT

Classification

According to epidemiologic criteria, chikungunya virus is arthropod-borne because it is transmitted by several species of mosquito. With the use of antigenic relationships demonstrated by hemagglutination inhibition and complement fixation, chikungunya is placed in the *Alphavirus* genus of the family Togaviridae.[38] Antisera prepared to chikungunya virus show strong cross reactions with *o'nyong nyong* by complement fixation and virus-dilution neutralization. Mayaro and Semliki Forest viruses, however, demonstrate only weak cross-reactions by hemagglutination inhibition and no reactions by complement fixation with chikungunya antigen. Cross-comparisons by plaque-reduction neutralization tests have shown little relatedness among alphaviruses.[75] Similar results have been obtained by fluorescent antibody technique.

Phylogenetic analysis of the E1 envelope glycoprotein from 18 strains divides chikungunya virus into two distinct genotypes corresponding to their geographic origin.[62,82] One chikungunya genotype consists of viruses from Senegal and Nigeria and represents the West Africa genotype. These viruses had only 78 to 85 percent nucleotide sequence identity to viruses of the South, Central, and East Africa genotype and the closely related Asian viruses. The phyletic grouping is consistent with the introduction of East African strains into Asia within a period 50 to 310 years ago.[62,80] The African and Asian strains of chikungunya virus are not antigenically separable with the use of mouse immune sera.[56] Although differences in plaque size and heat stability have been described between these strains, these differences might be due to the high number of mouse passages by the prototype African strain. Wild-type strains from all genotypes share the property of autointerference and production of hemorrhagic enteritis (Halstead, S. B., unpublished data, 1965).[28]

Morphology

Chikungunya virions are spherical particles approximately 42 nm in diameter.[34] They possess a lipid-containing envelope with fine projections. The central core, approximately 25 to 30 nm in diameter, is roughly hexagonal in cross section and contains a nucleocapsid of uncertain symmetry. Together with other alphaviruses, the genome is a positive-sense, single-stranded RNA of 12 kb that is messenger active and specifies the viral structural and nonstructural protein, including the polymerase. After an initial round of RNA replication, a subgenomic RNA of approximately 4 kb (26S RNA) is produced. This RNA encodes the viral structural proteins, which include two envelope and capsid proteins.[35] The gene is translated from the 5′ end, where genes for nonstructural proteins are located. Assembly of virus particles at the cell surface occurs by a budding process involving incorporation of the "core" virus precursor into virus particles.[34] Host-cell membranes are modified during infection and contain viral antigen when incorporated into viral envelopes. The protein hemagglutinin spikes are mounted on a phospholipid envelope.

Growth

Chikungunya virus produces death in infant mice, rats, and hamsters after intracerebral inoculation. Serial passage of the virus in mice has resulted in selection of a strain with a short incubation period that is lethal to weanling mice.[68] Virus grows to titers of 10^8 to 10^9 infectious doses per milliliter. Low-passage material is highly infectious for humans during routine laboratory handling, and therefore appropriate precautions should be taken by laboratory workers.

If a mouse brain seed suspension of low-passage virus is prepared and inoculated into other mice at a 1:5 or 1:10 final concentration, death may be delayed significantly, may be sporadic, or may not occur at all. This difference is due to autointerference.[28] Low-passage strains recovered in suckling mice characteristically demonstrate autointerference when inoculated at dilutions below 1:100.

Chikungunya virus produces a cytopathic effect in primary hamster kidney cells and in BHK-21, BSC-1, Vero, FL, HeLa, and rhesus kidney cells.[38] Virus multiplies in *A. albopictus*, *Aedes aegypti*, *Aedes vittatus*, *Anopheles stephensi*, and *Culex fatigans* continuous cell lines and in a cell line derived from *Drosophila*. Plaque assays have been described in LLC-MK2, Vero, and BHK-21 cell and in duck and chick embryos.[38]

TRANSMISSION

Chikungunya virus has been recovered from wild *A. aegypti* in Tanzania, Nigeria, India, and Thailand; from *Aedes africanus* in Uganda and Bangui; from *Aedes*

furcifer-taylori in South Africa and Senegal; and from *Aedes luteocephalus* and *Aedes dalzieli* in Senegal.* Occasional isolates have been recovered from *Mansonia fuscopennata* in Uganda and from *C. fatigans* in Thailand and Tanzania.

Transmission to humans has been demonstrated with the *A. furcifer-taylori* group; transmission to monkeys or mice has been demonstrated with *A. aegypti*, *A. albopictus*, *Aedes calceatus*, *Aedes triseriatus*, *Aedes togoi*, *Aedes pseudoscutellaris*, *Aedes polynesiensis*, *Anopheles albinanus*, *Mansonia africana*, *Erethmapodites chrysogaster*, and *Aedes apicoargenteus*.[38,48,60,71]

Using East African and related Asian chikungunya viruses, Tesh and colleagues[74] examined *A. albopictus* strains from 13 geographic locations from Hawaii to Africa and found considerable variation in susceptibility to infection by oral feeding. The 50 percent oral infective dose (ID_{50}) of a Hawaiian *A. albopictus* strain for a wild-type virus from India was $10^{5.4}$ plaque-forming units per milliliter. The amount of virus replicated by different mosquito strains varied between $10^{4.6}$ and $10^{7.4}$ plaque-forming units per mosquito. These observations, plus a mathematic model of chikungunya virus transmission developed by deMoor and Steffens,[24] suggest that major factors in determining the endemicity of chikungunya may be arthropod related. Tesh and associates[74] suggested that susceptibility to oral infection and the amount of virus replicated may be under genetic control, whereas deMoor and Steffens[24] found mosquito longevity to be the most important determinant in epidemic transmission of chikungunya. The 2005 to 2006 Indian Ocean pandemic evolved from an East African strain of chikungunya in which an A226V mutation enhanced ability of this virus to be biologically transmitted by *A. albopictus*. Subsequently, a further mutation occurred in E2-L210Q that enhanced fitness in *A. albopictus* and resulted in a second epidemic thrust.[79,80]

Serologic studies have demonstrated repeatedly the presence of antibodies in humans throughout the moist forests and semi-arid savannas of East and West Africa.[1,25,53,69] Until recently, most recorded chikungunya infections in humans have occurred in areas infested with *A. aegypti*. The epidemiology in these areas is similar to that of other *A. aegypti*–borne diseases and parallels the distribution of the vector. When *A. aegypti* mosquitoes are abundant in occupied dwellings, infection rates can be expected to be highest in women and children who are at home during daylight hours. When *A. aegypti* is found in public buildings, schools, and hospitals, outbreaks may involve persons in occupational patterns. Characteristically, *A. aegypti* chikungunya pandemics are explosive. Studying *A. aegypti* in laboratory mice, Rao and colleagues[64] documented mechanical transmission. Viremia in humans may be as high as 10^8 infectious doses per milliliter.[64] Because the extrinsic incubation period in *A. aegypti* is relatively long, the explosive nature of chikungunya outbreaks is explained best by mechanical transmission. The 2005 to 2006 outbreak on Reunion Island was unique in that *A. aegypti* was not found. This *A. albopictus*–borne outbreak, with a duration of around 4 months, affected an estimated 35 percent of a population of 800,000. [66]

*References 2, 19, 25, 37, 51, 53.

EPIDEMIOLOGY

Host Range

Chikungunya virus has the ability to replicate in a broad spectrum of vertebrate species. Newborn mice, hamsters, rats, rabbits, guinea pigs, and kittens all can be infected by subcutaneous inoculation of field strains of chikungunya virus,[14] which produces viremia, sickness, and, in most instances, death. Adult rabbits, mice, rats, and chickens inoculated peripherally have an asymptomatic viremia followed by an antibody response. Neutralizing or hemagglutination-inhibition antibodies to chikungunya have been recovered occasionally from sera obtained from ungulates. Attempts to infect cattle, goats, sheep, or horses experimentally failed to produce either viremia or an antibody response.[50] Vervet monkeys and baboons are infected readily. Rhesus monkeys were infected by intravenous and intramuscular inoculation and had viremia titers in excess of 10^7 mouse LD_{50}. *A. aegypti* transmitted virus to rhesus monkeys and could be infected by biting viremic animals.

Chikungunya antibodies have been found in vervet monkeys, baboons, chimpanzees, and red-tailed monkeys in Zimbabwe, South Africa, and Uganda.[47] The zoonotic status of chikungunya virus in Asia has not been studied carefully.

In Africa, zoonotic transmission to subhuman primates is surmised to take place in a wide variety of habitats, with transmission occurring in the forest canopy, at ground level, or both.[49] Chikungunya appears to be enzootic throughout much of eastern, central, southern, and western Africa.[38] Subhuman primate populations are affected in epizootics, which involve critical numbers of the susceptible population, followed by disappearance of the virus. Thus, chikungunya may maintain itself in wildlife populations by constantly moving epizootic activity, in much the same fashion as respiratory tract and enteric virus infections are maintained in humans. To expect that intercurrent and epidemic human infections in Africa are related to epizootic activity seems reasonable. Many putative or identified chikungunya vectors feed on humans as well as subhuman primates. Historically, chikungunya has emerged from its East African zoonotic focus to initiate Indian Ocean epidemics at intervals of approximately 30 to 50 years.[12] Although the 2005 pandemic was associated with genomic changes that increased vectoral capacity for *A. albopictus*, earlier pandemic viruses showed no such mutations.[80] A second series of outbreaks originated from Central-South African lineage strains causing outbreaks in Cameroon and Gabon in 2007.[81]

Geographic Distribution

When susceptible human and *A. aegypti* or *A. albopictus* populations are above the threshold level required for transmission, a person-mosquito-person cycle is established. This cycle probably is responsible for most

of the large urban outbreaks of chikungunya studied during the past 40 years. In Africa, chikungunya outbreaks have been reported from Uganda, Tanzania, Zimbabwe, South Africa, Angola, Zaire, Nigeria, Senegal, Madagascar, and Reunion.[38,64] This distribution best fits the present location of virus research laboratories. A reasonable assumption is that chikungunya is endemic throughout sub-Saharan Africa.

According to historical evidence, chikungunya has spread from the African enzootic focus and caused large pandemics throughout both the Asian and American tropics.[12,18,72] Pandemics swept India in 1824, 1871, 1902, 1923, 1963 to 1964, and 2006, with Sri Lanka (formerly Ceylon) involved in 1965.[12,40] In the 18th and 19th centuries, chikungunya epidemics were reported in the Indonesian archipelago. An extensive serologic survey using the plaque-reduction neutralization test has suggested chikungunya activity possibly during World War II in Kalimantan and Sulawesi, Indonesia. During the late 1950s and early 1960s, chikungunya appears to have established itself endemically in Southeast Asia and was transmitted continuously in urban populations in Thailand, Cambodia, and South Vietnam, possibly into the 1970s.[15,30,83] Involvement of urban populations in Burma appears to have been intermittent, with outbreaks recorded in 1963 and from 1970 to 1973.[52] A large chikungunya epidemic affected much of Indonesia in 1983 and 1984 and Burma in 1984 and 1985.[77] Chikungunya virus was isolated in Australia in 1989.[31] Serologic evidence of chikungunya virus infection has been found throughout the Philippines, possibly during World War II; since then, localized outbreaks have occurred in Manila, Philippines, in 1967 and Negros, Philippines, in 1968[3,11,44] and as recently as 1986.[17] From 1990 to 1995, chikungunya remained endemic at low levels in Thailand, Myanmar (formerly Burma), and Indonesia.[76] Little or no chikungunya virus infection was reported in the 20th century in Papua New Guinea, the Solomon Islands, Vanuatu (formerly New Hebrides), the Caroline Islands, the Pacific Islands, or any of the American tropics.[74]

A pertinent question to ask is why chikungunya and dengue viruses, both transmitted by *A. aegypti*, do not have an identical geographic distribution? The question may be answered partially by differences in the transmission of chikungunya and dengue. The threshold for infection of chikungunya virus in *A. aegypti* is relatively high, with approximately $10^{5.6}$ mouse infectious doses required to infect 50 percent of adult females.[74] The infection threshold of female *A. aegypti* for dengue virus is rather similar. However, *A. aegypti* mosquitoes infected with chikungunya virus transmit virus to vertebrates poorly, whereas dengue-infected mosquitoes transmit with great regularity.[27] Thus, transmission of chikungunya virus would be expected to occur only in areas with high human susceptibility rates and consistently high densities of *A. aegypti* and possibly by mechanical transmission.

CLINICAL MANIFESTATIONS

The incubation period of chikungunya fever is usually 2 to 4 days. In infants, the disease typically begins with the abrupt onset of fever, followed by flushing of the skin. Febrile convulsions may occur in as many as one third of patients. After 3 to 5 days of fever, a generalized maculopapular rash and lymphadenopathy are noted. Conjunctival injection, swelling of the eyelids, pharyngitis, and signs and symptoms of upper respiratory tract disease are common. No enanthem occurs. Febrile convulsions are noted frequently. Some infants have a biphasic fever curve, and arthralgia may be quite severe, although it is not seen frequently.[8,13,29,36,58]

In older children, fever develops acutely and is accompanied by headache, myalgia, and arthralgia involving various joints. Residual arthralgia is uncommon. An early macular blush and a maculopapular rash accompany or immediately precede defervescence. At the same time, marked lymphadenopathy occurs. Febrile convulsions are observed commonly. Hemorrhagic findings, including a positive tourniquet test, are rare.[7,13,29,36,58]

Arthralgia or arthritis is the most conspicuous feature of chikungunya in adults. Usually, patients can identify the precise time and the joint first affected in a chikungunya illness. Swelling and redness of joints and even the pinnae of the ear may occur.[13] The distal lower joints are most frequently involved.[6] During the Reunion Island outbreak excess deaths in the elderly accompanied chikungunya infections.[65]

Although dengue and chikungunya illnesses are similar, important distinguishing features are summarized in Tables 174D-1 through 174D-4 from clinical data obtained from children in Thailand.[29,58]

Table 174D-1 shows the abrupt onset and early severity of chikungunya versus dengue illnesses, many of which came to medical attention only several days after the onset of fever.

Chikungunya virus infections are shorter in duration than dengue virus infections (see Table 174D-2). Almost half of children with chikungunya had a fever that ended within 72 hours after onset, whereas the median duration of dengue fever was 2 days longer.

Many constitutional signs and symptoms occur with similar frequency in chikungunya and dengue viral infections and cannot be used to differentiate the illnesses clinically (see Table 174D-3). However, a terminal maculopapular rash, arthralgia or arthritis, and conjunctival injection were more common symptoms in chikungunya than in dengue (see Table 174D-4). Shock has been reported infrequently in chikungunya.[13,70,78] It was not observed in Thai cases.[58] Changes in taste perception and bradycardia, depression, or asthenia after illness are found rarely in chikungunya; these manifestations are distinctive findings in patients with dengue.

Hemorrhagic phenomena rarely occur with chikungunya virus infection. The frequency of hemorrhagic findings in chikungunya and primary and secondary dengue viral infections in Thai children is compared in Table 174D-5. The frequency of minor hemorrhagic manifestations in outpatient and inpatient dengue did not differ significantly from that in chikungunya cases. However, petechial rash and spontaneous hematemesis or melena developed in only hospitalized dengue cases.

PATHOGENESIS AND PATHOLOGY

The pathologic process of fatal human chikungunya illness has not been studied extensively.[78] Wild-type chikungunya strains produce a hemorrhagic enteritis in mice and hamsters.[28] Recently, a C57BL/6J mouse model involving arthritis, tenosynovitis, and myositis and a cynomolgus monkey model with long-duration chikungunya joint infection have been described.[54,39] In monkeys, chikungunya virus replicated in primary monocyte derived macrophages and joints, muscles, lymphoid organs, and liver.[39] Chikungunya antigens have been detected by immunohistochemistry in muscle satellite cells of muscle biopsies from two patients with a myositic syndrome[59] and in fibroblasts of the joint capsule, skeletal muscle, and dermis from a fatal neonatal case.[20] Chikungunya virus infects and persists in human cornea tissue, and viral infection has been transmitted surgically.[21] In vitro studies have shown that other cell types, such as human epithelial and endothelial cells, primary fibroblasts, and, to a lesser extent, monocyte-derived macrophages, are also able to sustain productive CHIKV infections.[20,39]

DIAGNOSIS

The differential diagnosis includes the viral causes of dengue fever syndrome.[41] In Australia and the western Pacific area, Ross River fever is a frequent cause of epidemic, arthropod-borne, viral arthralgia.

With the use of classic test methods, the diagnosis depends on demonstrating a significant increase in antibody after an illness. Ordinarily, a serum sample collected within 5 days of the onset of fever will not contain antibodies measured by IgM-capture enzyme-linked immunosorbent assay, hemagglutination-inhibition, complement-fixation, or neutralization tests.[4] However, virus or viral RNA usually can be identified in blood taken before 7 days after onset of fever.[4] Neutralizing and hemagglutination-inhibition antibodies generally are present in samples collected 2 weeks or more after the onset of fever. From a single serum sample collected 7 or more days after onset, detection of antibodies of the IgM class is possible with IgM capture enzyme-linked immunosorbent assays.[4,10,77] Neutralizing antibody can be

*Number positive/number of observations.

measured by the virus-dilution method in suckling mice (or weanling mice with use of the Ross high–mouse passage strain) or by the serum-dilution method in a variety of tissue cultures or plaque assay techniques.

Virus may be isolated by inoculating acute-phase serum or other suspect materials intracerebrally in 1- to 2-day-old mice or in tissue cultures. On initial passage, death may occur within 2 to 5 days after inoculation. An autointerference phenomenon is noted if low-dilution passages of infected mouse brain are performed. Passage at a 10^{-3} dilution or higher avoids this effect.

Vero cells and suckling mice are equally effective for primary isolation.

TREATMENT

Treatment is supportive. Antirheumatoid drugs may be effective for management of chronic arthritis; however, chloroquine phosphate 250 mg/day, once touted for management of acute arthritic pain, had no effect in a double-blinded trial.[23]

Bed rest is advised during the febrile period. Antipyretics or cold sponging should be used to keep the body temperature below 40° C (104° F).

Analgesics or mild sedation may be required to control pain. Arthritis after illness may require continued treatment with anti-inflammatory agents and graduated physiotherapy. Salicylates, because of their hemorrhagic potential, are contraindicated.

Febrile convulsions are treated with phenobarbital given intravenously or orally and continued until the temperature is normal. Severe or intractable convulsions may respond to intravenous diazepam.

Children who have lost excessive fluid because of vomiting, fasting, or thirsting and who cannot take oral fluids may require intravenous rehydration. Individuals with severe hemorrhagic phenomena should be studied for underlying hemostatic disorders.

PROGNOSIS

In a few instances, isolation or serologic evidence of recent infection has been obtained in persons with severe hemorrhagic findings and in individuals dying during an acute febrile illness.* In addition to hemorrhage, neurologic and myocardial involvement have been reported during chikungunya infection in adults.[13,16,20] In adults, arthralgia may persist for weeks, and exercise may prolong this symptom. Typically, pain shifts from joint to joint and is worse in the morning and on first use of the joint. Swelling of ankles, wrists, and fingers occurs frequently. In older patients, the sequelae may resemble rheumatoid arthritis.[6] In the Reunion Island outbreak, 57 percent of adult patients experienced long-duration symptoms, half of which impaired daily activities.[73] Chronic rheumatic manifestations were associated with age, severity of initial acute illness pain, and presence of osteoarthritis.[73] A destructive arthropathy after illness has been reported.[7,46] Chikungunya virus infection might coincide with other pathologic processes and result in death of the individual.[55,65] Carefully studied, virologically documented cases have shown neither thrombocytopenia nor severe neutropenia.[36,46] Until more is known of the pathogenesis of chikungunya virus infection, estimating the frequency with which death can be attributed directly to chikungunya fever will be difficult.

Infants with chikungunya may experience residual neurologic deficits after febrile convulsions.[20]

PREVENTION

Formalin-treated chikungunya virus (Ross strain) grown in African green monkey kidney cells produces a satisfactory immune response and resistance to challenge when administered in three divided doses in monkeys.[32] A vaccine prepared under similar conditions produced hemagglutination-inhibition, complement-fixation, and neutralizing antibody responses in susceptible human volunteers.[33] A comparative study from the same laboratory was made of formalin-inactivated chikungunya vaccines prepared from the virus propagated in African green monkey kidney monolayers and concentrated chick embryo suspension cultures.[84] The latter vaccine was significantly more protective to mice against live homologous virus challenge and stimulated the production of four to five times more circulating antibodies than did the vaccine prepared with virus grown in African green monkey kidney cultures. Nakao and Hotta,[57] studying chikungunya grown in BHK-21 cells, found that ultraviolet-inactivated preparations were significantly more immunogenic than formalin-treated virus. Tween-ether–extracted virus preparations also have been found to be immunogenic. A live attenuated chikungunya vaccine has been developed,[42] as have DNA and chimeric vaccines.[22,45] In view of sporadic outbreaks and low mortality associated with chikungunya virus infection, commercial production of a chikungunya vaccine is likely to have a low priority.

At present, prevention consists of avoiding mosquito bites. For urban outbreaks in most of the Asian and African tropics, the regimen for individual protection and for chronic and emergency control is the same as has been described for dengue. When other vectors are involved, measures designed to combat *A. aegypti* may fail. In such outbreaks, expert entomologic advice will be needed to design appropriate preventive measures.

For discussion of control of mosquitoes, epidemic measures, and health education, see Chapter 175.

174E ■ ROSS RIVER VIRUS ARTHRITIS

John G. Aaskov

"Epidemics" of a benign disease causing polyarthralgia and rash were first described in Australia in 1927.[63] Following the recovery of the causative agent and the advent of serologic tests able to diagnose Ross River virus infection, epidemic polyarthritis has been recognized as endemic in Australia and has occurred as epidemics in numerous Pacific nations. Approximately 4000 cases of epidemic polyarthritis are reported in Australia each year, with a peak of 7800 cases in 1996.

Some confusion has been generated recently by use of the term *Ross River fever* to describe clinical Ross River virus infections because fever does not develop in more than half of those with clinical disease.[59] Additional confusion has been generated by efforts to describe any polyarthritis caused by an Australian arbovirus as epidemic polyarthritis. The term *epidemic polyarthritis* should be used to describe only clinical disease caused by the Ross River virus.

ETIOLOGIC AGENT

Investigations of an epidemic of polyarthritis in southern Australia in 1956[13,74] suggested that an alphavirus was the causative agent. This was confirmed when Ross River virus was isolated from *Aedes vigilax* mosquitoes collected beside Ross River, near Townsville in northern Australia, and shown, on serologic grounds, to be the causative agent of epidemic polyarthritis.[24,27] Although the first isolation of virus from a human was from a febrile child

without arthritis,[23] subsequent use of mosquito cell lines enabled Ross River virus to be recovered regularly from epidemic polyarthritis patients.[11,28,68,77]

Ross River virus is related serologically to Getah and Bebaru viruses in the Semliki Forest virus subgroup.[21] Nucleotide sequencing has confirmed this close relationship among Ross River, Getah, and Semliki Forest viruses.[67] Phylogenetic analyses have identified four lineages of Ross River virus, three of which appear to have become extinct.[45] The appearance of the present lineage was associated with major genetic arrangements in the *NSP3* gene of Ross River virus.[7] No association has been observed between any particular virus genotype and disease in humans, but this may be due to most studies employing consensus nucleotide sequences for what genetically are very diverse viral populations.[53]

Cryoelectron microscopic studies[17,66,79] suggest that the nucleocapsid of Ross River virus is approximately 400 Å in diameter and has a T = 4 quaternary structure. It is surrounded by a membrane bilayer that is penetrated by 80 spikes, also arranged in a T = 4 lattice. Each spike is a trimer of heterodimers of the envelope glycoproteins E1 and E2. The E2 protein makes contact with heparin on the surface of host cells, and antibodies that combine with this protein neutralize infection in vitro.[2,75,78]

The virus can be adapted to grow to high titer in the muscle and brain of day-old mice, in which it causes paralysis and death.[56,60] Ross River virus also grows to high titer in vertebrate and mosquito cell lines.[11]

TRANSMISSION AND EPIDEMIOLOGY

Ross River virus is endemic in all mainland states of Australia and in Papua New Guinea. The incidence of epidemic polyarthritis is highest in the Australian states of Queensland, Northern Territory, and Western Australia, with other states experiencing outbreaks of infection against a background of low incidence (http://www.health.gov.au/internet/main/publishing.nsf/Content/cda-surveil-nndss-nndssintro.htm). No transmission of Ross River virus had been reported from the Pacific island states involved in the 1979 to 1980 epidemic (i.e., Fiji, Samoa, Tonga, Cook Islands)[8,28,49,68,77] until 2003, when cases of epidemic polyarthritis began to be detected in travelers who had visited Fiji.[50] Sporadic cases, without local virus transmission, have occurred in Europe and the United States in tourists and military personnel returning from Australia.

Isolation of Ross River virus from more than 20 species of mosquitoes,[69] in particular *A. vigilax*[27,39] and *Culex annulirostris*,[26,39] and the presence of antibody to the virus in almost as many species of animals, particularly mammals,[24,25] suggested a mammal-mosquito cycle with humans as an incidental host. However, improved laboratory diagnostic services have shown clinical infection in humans occurs year-round, although most cases are seen in the late summer and in autumn, and most patients are city dwellers.[10,59] Taken together with the explosive spread of disease during the 1979 to 1980 epidemic of Ross River virus infection in the Pacific,[8,28,68,77] this virus appears to be maintained in either of two cycles, mammal-mosquito-mammal or human-mosquito-human, with movement of virus between the two. Evidence also has been obtained of transovarial transmission of Ross River virus in *Aedes* mosquitoes.[48,52]

Patients may be viremic for up to 7 days after the onset of symptoms.[10,68] The incubation time from infection to the onset of symptoms may vary from 1 to 27 days, 7 to 9 days being the usual interval in endemic areas.[32]

In endemic areas, the ratio of subclinical to clinical infection may be as high as 50:1,[10] but during outbreaks, the ratio can be reduced to 4:1 or less.[8,41] Approximately 1.5 percent of humans living in northern Australia are infected with Ross River virus each year,[10] but the rates are much higher in some areas.[19,20]

Infection rates are the same in both sexes, and early reports that clinical disease was more common in females than in males[22,59] are not supported by Australian national data for the past decade. An association between human leukocyte antigen (HLA)-DR7 and clinical disease also has been observed.[38]

Ross River virus has been shown to cross the placenta in mice[6] and humans.[9] In mice, the result is extensive postpartum mortality,[6] but in humans, no evidence of morbidity or mortality in children infected in utero has been found.

CLINICAL MANIFESTATIONS

Epidemic polyarthritis occurs as a mild to severe illness characterized by joint pain, particularly in the knees and the small joints of the hands and feet.* Frequently, the joint pain is accompanied by a maculopapular or vesicular rash on the trunk and limbs and sometimes by fever, chills, or both. Sore throat, lymphadenopathy, paresthesia, tenderness of the palms and soles, exanthems, and, more rarely, petechiae have been observed. Most patients experience several weeks of painful arthritis followed by a slow decrease in the severity of symptoms during the 30 to 40 weeks required by most for recovery.[5] Infrequently, symptoms may persist for a year or more,[30] and some patients may experience episodes of severe arthritis during convalescence. One study has linked Ross River virus infection to a chronic fatigue syndrome.[44]

In a small proportion of patients (<0.1%), clinical disease may develop without arthritis.[23] Rare cases of glomerulonephritis,[35] hematuria,[14] and central nervous system symptoms[1,54,65,70] accompanying Ross River virus infection in humans also have been reported.

The severity and duration of symptoms are age related. Most clinical disease occurs in adults, who also have the most severe and prolonged symptoms. Teenagers may be incapacitated for only a few days and asymptomatic after 1 to 2 weeks.

The only other species known to develop clinical disease (musculoskeletal symptoms) after a natural infection with Ross River virus is equines.[15]

*References 13, 22, 24, 29, 30, 40, 59, 61.

PATHOLOGY

The pathogenesis of Ross River virus disease in humans is not understood. The literature describing the pathologic process of Ross River virus infection in mice is extensive,* but almost invariably, clinical symptoms are observed only in mice infected when less than 4 weeks of age, which have key immunologic genes silenced, or which are infected by routes that could not occur in nature and with strains of virus that have been passaged extensively in cell culture.

Synovial tissue from patients with epidemic polyarthritis may show a marked mononuclear leukocyte infiltrate with small amounts of fibrin deposition and synovial cell hyperplasia.[42,76] No virus or viral antigen has been detected in synovial tissue from patients with epidemic polyarthritis, but a 250-nucleotide fragment of the viral genome was detected by reverse-transcription polymerase chain reaction (RT-PCR) in synovium from 2/12 patients 5 weeks after the onset of symptoms.[76] Ross River virus has been shown to replicate for a similar period in human synovial cells maintained at 35° C (95° F) in vitro.[46] Whether virus persists in joints as long as symptoms are present remains unclear, and ethical and technical constraints prevent this issue being explored in a systematic manner.

Fluid from affected joints consists almost entirely of mononuclear leukocytes at all stages of disease.[18,31,33] Human synovial fibroblasts infected with Ross River virus in vitro produce elevated levels of messenger RNA (mRNA) coding for chemoattractants and other mediators, such as monocyte chemoattractant protein 1, interleukin-8, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor–α, but elevated levels of the proteins for which they code have not been demonstrated.[55]

No evidence of immune complexes or complement activation in arthritic joints has been found, and viral antigen can be detected (in macrophages) for only 5 to 7 days after the onset of symptoms, despite the persistence of arthritis for 30 to 40 weeks.[34] No significant levels of anticollagen antibodies could be detected in serum from epidemic polyarthritis patients.[37] Neither anti–Ross River virus antibody levels nor a primary, virus-specific, cell-mediated immune response to Ross River virus infection correlated with the presence or absence of arthritis in human infections.[3] In patients with epidemic polyarthritis, a nonspecific immunologic response (natural killer cells) correlated well with the presence or absence of arthritic symptoms.[3,5] Functional natural killer cells have been recovered from the knee of a patient with epidemic polyarthritis,[42] and natural killer cells have been found to kill autologous synovial tissue in vitro.[5]

A rash develops in approximately 30 percent of patients with epidemic polyarthritis.[59] The dermis underlying these lesions contains a perivascular infiltrate of CD8+ T cells and some monocytes and macrophages.[36] No immunoglobulin or complement deposition has been observed in these lesions, although Ross River virus antigen was detected in basal epidermal and eccrine duct epithelial cells.[36]

*References 43, 51, 56-58, 60, 71.

DIAGNOSIS

The signs and symptoms of a Ross River virus infection (see earlier discussion) are too nonspecific to permit establishment of a diagnosis on clinical grounds alone. Most clinical diagnoses of epidemic polyarthritis are confirmed by use of an indirect enzyme-linked immunosorbent assay (ELISA)[64] to detect Ross River virus–specific IgM antibodies in serum collected 7 to 10 days after the onset of symptoms. Various forms of this assay are available from commercial suppliers. Immunoglobulin (Ig)M can be detected for approximately 3 months after the onset of disease.[10]

In rare cases (perhaps <1/5000), anti–Ross River virus IgM antibody production may persist for years. Assays for serum anti–Ross River virus IgA might be an alternative to IgM assays because the duration of IgA production is shorter than that for IgM.[16] However, such IgA assays have not been adopted by routine diagnostic laboratories. More recently, indirect ELISA assays that measure the avidity of anti–Ross River virus antibody have been shown to be able to discriminate between recent and old infections with this virus.[47]

Although virus sometimes can be isolated from seronegative, acute-phase sera,[8,11,28,68,77] this procedure is not performed in most routine diagnostic laboratories. RT-PCR protocols,[73] mostly unpublished, have been developed for the detection of Ross River virus RNA, but they are less sensitive than is virus isolation for the detection of virus and are not used routinely for the diagnosis of human disease.

Because epidemic polyarthritis is an arthritic disease, care must be taken to avoid false-positive results caused by the presence of rheumatoid factor when indirect ELISA is used to detect anti–Ross River virus IgM antibodies. Such precautions include removal of IgG or rheumatoid factor before testing sera or performing tests for rheumatoid factor in parallel with ELISA.

Another source of false-positive diagnoses is the production of anti–Ross River virus IgM antibody caused by polyclonal B-cell activation after infection of a Ross River virus–immune host with Epstein-Barr virus, cytomegalovirus, *Coxiella burnetii*, or *Plasmodium* spp.

Other viral infections to be considered when a patient is suspected of having epidemic polyarthritis include infections with Barmah Forest, Sindbis, Kunjin, or rubella viruses.

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available, although experimental evidence suggests that interferon-γ may ameliorate acute disease.[72] Nonsteroidal anti-inflammatory medication or steroids have been used to treat patients with severe disease or prolonged symptoms, but the efficacy of such treatment has not been evaluated in any

systematic manner. A small study found that patients taking corticosteroids recovered more quickly than those using nonsteroidal anti-inflammatory medication.[62] Rest, while maintaining mobility and muscle tone, appears to provide significant relief.

Epidemic polyarthritis has not been shown to progress to chronic joint disease.

PREVENTION

A killed virus vaccine[4] was found to be safe and immunogenic in phase I and II clinical trials[12] and completed phase III trials in 2013. In urban areas, public health mosquito control programs reduce mosquito numbers, but prevention of mosquito exposure for those with outdoor occupations and pastimes is impossible. Personal protection (i.e., insect screening of houses, wearing of protective clothing, and application of insect repellents) is the only reliable way to avoid the risk for being infected.

Theodore F. Tsai

O'NYONG-NYONG

The virus name *o'nyong-nyong* is derived from the Acholi term meaning "very painful and weak," which describes the acute constitutional symptoms and polyarthritis associated with the disease of the same name.[14] The virus is related closely to chikungunya virus, but unlike most arboviruses, it is transmitted by anopheline mosquitoes in an interhuman cycle analogous to that of malaria in rural Africa. Apart from the human-to-human epidemic cycle, the natural transmission cycle and involvement of other vertebrate hosts are largely unknown. The disease first came to attention in, arguably, the largest arboviral epidemic ever recorded. After emerging in Uganda in 1959, the epidemic spread to South and West Africa and produced an estimated 2 million cases before the outbreak died out spontaneously 3 years later. The disease apparently had disappeared from East Africa, although the virus was isolated sporadically from mosquitoes until 1996, when only the second ever recognized outbreak appeared, in Uganda.[14] In retrospect, the virus had been circulating at low levels in the area several years before this epidemic occurred. Human and animal infections have been documented serologically in Nigeria, Sierra Leone, Ghana, and Chad. Factors underlying emergence of the virus, its natural reservoir, and the reasons for its disappearance can only be surmised, but exhaustion of susceptible human hosts is a likely explanation for the cessation of epidemic transmission. Clinically, the disease is similar to chikungunya, although lymphadenopathy is more pronounced and mimics, in some cases, the enlarged cervical lymph nodes of sleeping sickness.[2] Virus can be isolated from acute-phase blood samples, or the diagnosis can be confirmed serologically by detection of specific immunoglobulin (Ig)M. Personal protective measures against malaria (e.g., use of bed nets) should be effective against acquiring infection.

IGBO-ORA FEVER

Igbo-Ora virus has been determined genetically to be a subtype of o'nyong-nyong virus and, like it, is transmitted by anopheline mosquitoes and (without adaptation) is nonpathogenic in suckling mice.[21] The viral transmission cycle has not been defined. Sporadic cases and small outbreaks have been reported from Igbo-Ora and Ibadan, Nigeria, the Ivory Coast, and the Central African Republic. Based on a single case description, the illness consists of fever, polyarthritis, and pharyngitis.

BARMAH FOREST FEVER

Barmah Forest fever occurs only in Australia, where it has been a sporadic and occasionally hyperendemic infection leading to a polyarthropathy-rash illness indistinguishable from that of Ross River fever.[6,15,23] The mosquito-borne viral transmission cycle shares some features with that of Ross River virus; however, independent outbreaks have occurred in locations where both viruses are enzootic, thus indicating differences in their

transmission cycles or human susceptibility. Seroprevalence to Barmah Forest virus is generally lower. Anecdotal cases complicated by central nervous system signs and glomerulonephritis have been reported.[13,23] Serologic diagnosis is straightforward in most cases, with little cross reaction between the viruses.

SINDBIS FEVER

Sindbis virus was named after a district north of Cairo, Egypt, where it first was isolated. It is the prototype of an antigenic complex that also includes western equine encephalitis virus and several Sindbis viral subtypes, including Ockelbo and related strains isolated from Scandinavia and the Babanki strain from West Africa. Two genotypes consisting of the South African and Scandinavian strains and the Australian and Asian strains have been defined. The close genetic relationship of the South African and Scandinavian strains indicates a recent introduction to Europe, possibly by a migrating bird.

The virus is distributed widely over four continents, although only sporadic cases have been reported from Asia and Australia. Transmission is endemic and occasionally hyperendemic in Africa and Scandinavia. The virus is transmitted to birds by various species of *Culex* mosquitoes, and humans are infected when virus transmission "spills out" of the enzootic cycle by the intervention of bridging vectors that feed on viremic birds and later on humans.

Endemic infections occur with varying intensity in areas of Africa.[11,19] Seroprevalence rates range from a few percent to 20 percent in some areas. Outbreaks producing hundreds to thousands of cases have been described. Concurrent transmission with West Nile virus, transmitted in the same avian cycle, is common. In South Africa, transmission occurs during the austral summer from December to April. Infections rarely may be acquired during travel.[4]

An endemic focus in Scandinavia (between 60 and 63 degrees latitude in Sweden) was recognized after a series of outbreaks in 1981 led to several hundred cases in Sweden, Norway, Finland, and adjacent areas of western Russia called, locally, Ockelbo fever, Pogosta disease, and Karelian fever.[5,16,27] Seroprevalence is low, around 5 to 10 percent. By estimation from seroprevalence rates, 600 to 1200 clinical cases may occur annually in Sweden alone. Serosurveys indicate a wider distribution of unrecognized infection in Northern and Central Europe. Most cases occur from July to September in middle-aged adults exposed to forested areas while picking berries or mushrooms or during other recreational activities. Outbreaks in Finland seem to peak at 7-year intervals, associated with the size of grouse populations.

Acute arthralgia and rash are the principal features of the illness. They may be preceded by mild fever, headache, and myalgia, but patients may have arthralgia alone, and children may exhibit fever and nonspecific symptoms alone. The joints, especially the ankles, wrists, knees, fingers, and toes and less often the hips, shoulders, elbows, neck, and back, are involved symmetrically. The joints appear swollen, and movement is limited. The Achilles and wrist tendons may be inflamed, as well, sometimes causing nerve entrapment and paresthesias. Some patients are confined to bed and unable to walk, but typically, the joint pain and stiffness lead to a lesser degree of discomfort and compromised function. A fine papular and sometimes pruritic rash appears on the trunk and extremities (including the palms and soles) but usually spares the face and head, and after a few days the rash develops a stained appearance and disappears. Lesions on the hands and feet may vesiculate. Joint symptoms resolve within 3 to 4 months in approximately 60 percent of cases; however, in the remainder, symptoms may persist for 3 to 4 years.[12,20,24,25] A higher prevalence of *HLA-DRB1*01* and autoantibodies has been reported in patients with continued joint symptoms 3 years after the initial illness in contrast to a reference population.[25] Muscle biopsy from a patient with prolonged weakness and in vitro experiments suggest that the virus can infect and destroy myotubes and myoblasts.[24] Serologic evidence of infection in patients with central nervous system signs has been reported from China.[8]

The illness is not differentiated easily from West Nile fever, which is transmitted under similar epidemiologic circumstances, and has been mistaken for rubella. The diagnosis is confirmed serologically by detection of specific IgM in acute-phase serum samples. IgM is detectable for months in some patients. The virus can be isolated, but not reliably, from acute-phase capillary blood and skin lesions. Viral genomic products can be detected in skin biopsy samples.[10]

Symptomatic treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) is sufficient in most patients. Anti–tumor necrosis factor antibodies have exacerbated alphaviral infection in experimental animals and should be avoided. Persons who choose to enter sylvatic transmission foci in the summer should apply mosquito repellents and dress appropriately.

MAYARO FEVER

Endemic infections are highly prevalent in the forested areas of South and Central America, where Mayaro virus is transmitted among *Haemagogus* mosquitoes, marsupials, and small mammals, somewhat analogous to the jungle cycle of yellow fever.[7,28] Seroprevalence rates increase with age to higher than 50 percent in native populations in some locations. The virus was isolated first from sporadic fever cases on Trinidad and named after the island's Mayaro district.[1] Outbreaks have occurred in Bolivia, Pará (a state in Brazil), and Surinam, principally in men occupationally exposed to forested sites and in residents of adjoining villages, as well as in travelers returning from Central America.[3,22,26] Cases have been reported in travelers returning to the United States, Netherlands, France, and Germany. Epidemic transmission was reported in the city of Manaus, Brazil and is a risk in other *Aedes aegypti*–infested cities.[17] The virus is placed in the Semliki Forest antigenic complex; its Una subtype causes arthritis in horses.

The illness consists of acute polyarthritis and rash.[22] Joint swelling, pain, and stiffness principally involve the

hands, wrists, ankles, toes, elbows, and knees. The hands may be so swollen that they cannot be closed, and joints of the lower extremities may be so painful that patients limp or are unable to walk. Milder cases may occur, however. The morbilliform rash is difficult to distinguish from rubella, with individual or coalescent papular lesions occurring on the trunk and extremities and usually sparing the face. Rash occurs more often in children than in adults. Mild fever, pharyngitis, conjunctivitis, headache, lymphadenitis, and minor mucosal and petechial bleeding occur in some patients. The constitutional symptoms resolve rapidly, but the joint symptoms may wax and wane for several weeks or months. Pneumonitis and renal dysfunction that have been described in some cases may have been caused by concurrent infections. Transient leukopenia usually develops; some patients have had mild elevations in liver enzyme activities and bilirubin concentration. A fatal case of yellow fever was reported in a patient recovering from Mayaro fever.

The illness is differentiated from other tropical febrile illnesses with rash and musculoskeletal pain by the specific involvement of the joints and the sylvatic setting of exposure. Some patients have features closely resembling those of rubella. Virus can be isolated from acute-phase blood specimens, but laboratory confirmation by IgM serology is sensitive, specific, and more practical. Symptoms are treated with NSAIDs and rest. Repellents should be used when sylvatic-enzootic foci cannot be avoided.

SEMLIKI FOREST VIRAL INFECTION

Febrile illnesses with severe persistent headache have been reported from Central and West Africa, where Semliki Forest virus is transmitted principally by forest *Aedes* mosquitoes.[18] The virus appears to be a common cause of infection in horses, as well. The MeTri subtype has been implicated serologically in encephalitis cases in Vietnam; its transmission cycle has not been described. A fatal case of encephalitis in a laboratory worker has been reported.[9]

CHAPTER 175

FLAVIVIRUSES

175A ■ ST. LOUIS ENCEPHALITIS

Kimberly C. Martin • José R. Romero • Theodore F. Tsai

St. Louis encephalitis (SLE) virus was first identified in 1933 after an epidemic of encephalitis in St. Louis, Missouri during August 1933.[81] Before the 1999 introduction of West Nile virus, St. Louis encephalitis was the most important arboviral infection in the United States because of its leading role as a cause of widespread epidemics. Encephalitis is the principal clinical manifestation, although milder central nervous system (CNS) syndromes do occur, especially in children. The virus is transmitted between birds and *Culex* mosquitoes with humans serving only as incidental "dead end" hosts.

ETIOLOGIC AGENT

The SLE virus is a member of the genus *Flavivirus* within the Flaviviridae family of viruses. SLE belongs to the Japanese encephalitis virus antigenic complex, which also includes such important human pathogens as Japanese encephalitis virus, West Nile virus (WNV), and Murray Valley encephalitis virus.

Phylogenetic analysis of the E glycoprotein sequences from 62 strains from the United States and Central and South America identified seven genotypes corresponding to origins in the United States and South America.[52] Most recently, analysis of 133 strains, including 30 novel strains from Brazil, has identified an eighth putative genotype.[67] Individual clades can be identified within each genotype.

Genotype II is more prevalent in North America, and genotypes I and III to VIII are found distributed throughout the Americas.[67] The most genetically diverse strains differ by only 10.1 percent nucleotide divergence (2.8% amino acid variation) in the total E gene nucleotide sequence while strains within each lineage show less than 5.5 percent nucleotide divergence, thus indicating a highly constrained viral adaptation to vector and vertebrate hosts.[42] The nucleotide diversity exhibited by SLE is substantially less than that seen by other members of the Japanese encephalitis virus antigenic complex. Strains from the three principal genotypes in the United States (I, II, and V) differ in biologic characteristics; epidemic-associated strains from the Ohio and Mississippi river basins and Florida display greater virulence in mice than do strains from the western United States associated with an endemic pattern of transmission.[15,48] Multiple viral genotypes with distinct biologic characteristics may be transmitted in relatively delimited areas within a region as small as a county in some years and more widely in others.[15,31]

ECOLOGY

SLE virus is transmitted in an enzootic cycle among birds and *Culex* mosquitoes in three distinct cycles associated with its four principal vector species: *Culex tarsalis* in the western and central United States, *Culex pipiens* in the eastern and western United States, *Culex quinquefasciatus* in the east central and Atlantic states, and *Culex nigripalpus* in Florida. *Culex salinarius* and *Culex restuans* may have accessory roles in viral amplification and transmission (Fig. 175A-1).[12,36,39,46,77]

In the western United States, *C. tarsalis* serves as both an enzootic and epizootic vector. This species feeds chiefly on birds early in the summer and switches to mammalian hosts, including humans, in midsummer. The transmission cycles of SLE virus and WNV overlap throughout the United States. Sparrows, finches, and other small birds, and especially their nestlings, are the principal amplifying hosts.[44] In the West, human infections result from encounters with the vector along natural and artificial waterways, irrigated farmland, and other breeding sites found chiefly in rural agricultural areas.

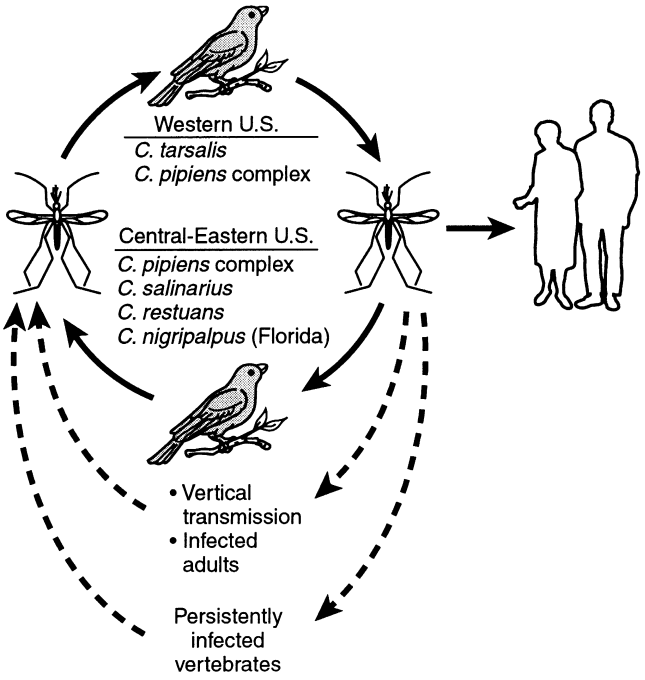

FIGURE 175A-1 ■ Transmission cycles of St. Louis encephalitis virus in North America. *Culex* mosquito vectors differ geographically: *C. tarsalis* in the West, *C. pipiens* and *C. quinquefasciatus* in the Ohio and Mississippi valleys, and *C. nigripalpus* in Florida. Epidemics occur when intense viral transmission in the enzootic cycle "spills over" and results in human infections. The viral overwintering mechanism, possibly in mosquitoes or persistently infected vertebrates, has not been proved *(broken lines).*

The recent introduction of West Nile virus into an overlapping transmission cycle may have an effect of modulating SLE virus transmission because West Nile virus–infected birds are more refractory to development of infection and viremia with SLE virus than the reverse.[24]

In the Ohio and Mississippi valleys and on the Gulf Coast, infections are acquired in the peridomestic environment, where *C. pipiens* and *C. quinquefasciatus* are, respectively, the enzootic vectors in northern and southern states. The mechanism by which the virus overwinters is not known; however, SLE virus has been shown to persist in overwintering *C.* tarsalis and *C. pipiens* for more than a month.[4] Additionally, vertical or transovarial transmission has been detected under laboratory conditions in *Culex* species.[4,26,42]

The intermittent occurrence of urban SLE outbreaks has been associated with climatic factors, such as a severe winter freeze in the 1 to 2 years before an outbreak or an antecedent mild winter, wet spring, and dry hot summer.[19,46] Snowpack and the resultant availability of irrigation water and an area supportive of mosquito breeding appear to be highly predictive of viral transmission in southern California.[82] In a model of global warming, SLE transmission is predicted to move to northern latitudes and, in existing endemic areas, to become seasonal in the spring and fall.[61] Periods of drought followed by a briefer wet interval have been associated with viral transmission in Florida.[18,70]

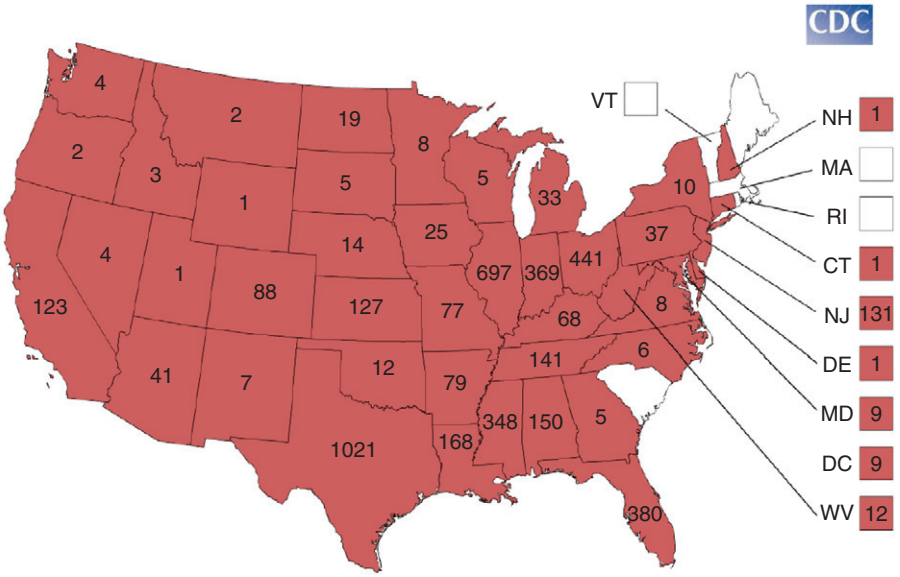

FIGURE 175A-2 ■ Reported case of St. Louis encephalitis virus neuroinvasive disease* by state, 1964 to 2010. Cases reported by state of residence. (See companion Expert Consult website for color version.)

*Neuroinvasive disease includes encephalitis, meningoencephalitis, or meningitis.

EPIDEMIOLOGY

The epidemiologic patterns of SLE virus transmission reflect human interactions with reservoirs of the virus and its principal mosquito vectors.[35,37,46,77] In western states (Fig. 175A-2 and 175A-3), perennial transmission of SLE virus leads to an endemic pattern of transmission, but epidemics are limited by a high level of immunity in the population.[63,79] Infections occur chiefly in rural areas in association with the habitat of the vector. SLE outbreaks have taken place typically in rural agricultural areas and their small towns.[34] Studies in Texas indicated that an overlap of urban and rural cycles contributed to an urban outbreak in Dallas after introduction of the virus to the urban *C. quinquefasciatus* cycle from rural *C. tarsalis*.[28,35,36]

Epidemics frequently have occurred in urban locations or their peripheries. In 1975, a nationwide epidemic led to outbreaks in Houston, Chicago, Memphis, and Detroit, as well as smaller outbreaks in rural towns throughout the South and Midwest (Fig. 175A-4). Outbreaks in large urban centers generally have been associated with attack rates of fewer than 40 cases/100,000 residents and often have clustered in low socioeconomic status areas, the most recent example occurring in Louisiana in 2001.* In recent urban outbreaks, homelessness and infection with

*References 17, 28, 30, 46, 58, 77, 78, 84.

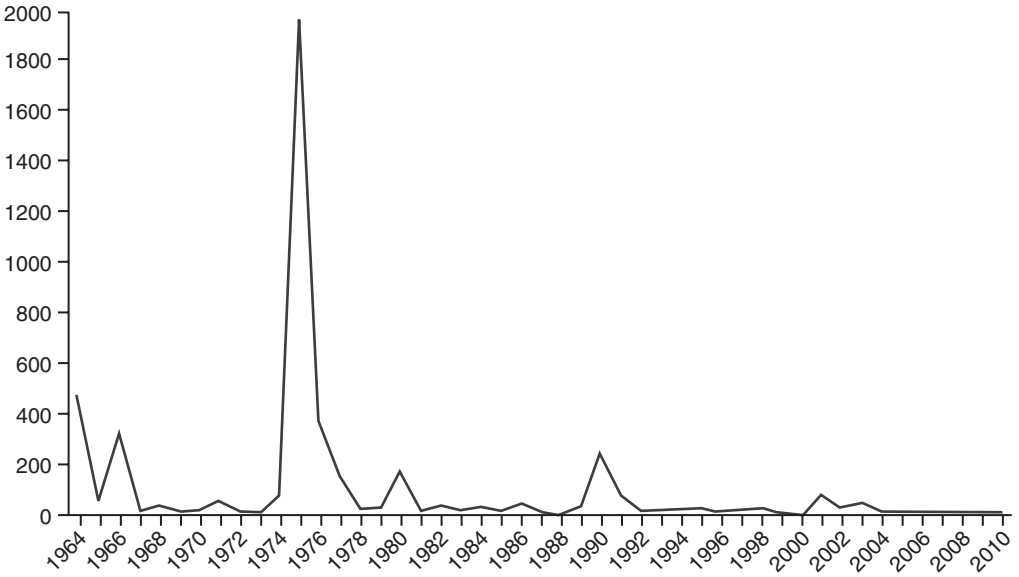

FIGURE 175A-4 ■ Reported St. Louis encephalitis cases by year, United States, 1964 to 2010. A nationwide epidemic in 1975 produced more than 2000 cases.

human immunodeficiency virus (HIV) have been the principal risk factors for acquiring SLE.[55,80] However, in the 1933 St. Louis outbreak, attack rates were highest in wealthy areas where open sewers, streams, ponds, and weeds were prevalent; and in other outbreaks, lush vegetation around houses, which provides shelter for *C. nigripalpus*, and closed sewer systems clogged with grass clippings were factors associated with high attack rates in upper socioeconomic areas.[18,45]

In outbreaks of disease from *C. pipiens* and *C. quinquefasciatus*, epidemic attack rates are 1.2 to 3 times higher in females than in males, possibly reflecting increased exposure of females to these peridomestic vectors,[41,46,78] whereas in western *C. tarsalis*–borne outbreaks, attack rates are usually higher in males.[34,63] A similar observation has been made in Florida, where SLE attack rates are highest in working-age males.[20,45,53] *C. nigripalpus* and *C. tarsalis* are most active in the twilight hours, and outdoor activity during these periods is associated with a greater risk for exposure.

Most cases (>80%) occur during the months of July through September.[62] However, in Florida, epidemics have continued through mid-December.[45,69] In the 1975 nationwide epidemic, outbreaks appeared first in the southeastern states in June, followed by an appearance in northern foci later in the summer and fall.[46]

From the introduction of WNV into the United States in 1999 through 2010, only 215 cases of neuroinvasive SLE virus disease were reported to the CDC.[11,62] Five states accounted for nearly 90 percent of cases during this period—Louisiana, Texas, Arizona, Michigan, and Mississippi (see Fig. 175A-2).[13,62] However, within states reporting SLE infections, cases are geographically restricted (see Fig. 175A-3). A median of eight cases per year were reported nationwide from 2002 to 2011. The annual incidence of neuroinvasive SLE peaked in 2001 (0.27/100,000 population) and fell to an average low of 0.001/100,000 in 2005 to 2007.[62] Reemergence of SLE in areas where it had been absent for decades has been noted. In 2010, the District of Colombia reported two cases of non-neuroinvasive SLE. These were the first case reports from this jurisdiction since 1975.[13] Only Alabama and Arkansas reported cases of neuroinvasive disease (N = 4) in 2011. It is unknown if the recent decrease in the number of reported cases of SLE is due to normal periodicity in SLE virus activity, surveillance artifact, or environmental displacement of the virus by West Nile virus.

Although a case of neuroinvasive SLE in an infant as young as 19 days has been reported, the most important risk factor for acquiring neuroinvasive disease is advanced age.[37,46,83] Age-specific attack rates are lowest in children and rise steadily in adulthood, with attack rates 5 to 40 times higher in persons older than 60 years than in those younger than 10 years. During outbreaks, infections occur uniformly in all age groups, with as many as 300 asymptomatic infections for each clinically apparent case. Therefore, the higher clinical attack rates in the elderly are a function of susceptibility and not exposure.[37,46] The clinical expression of illness is more severe and the case-fatality rate is also highest in the elderly. The biologic basis for this age-related risk probably reflects aging of the immune system, as well as comorbidities compromising cerebrovascular integrity.[10]

In the West, where SLE infections are endemic, an increasing level of immunity associated with length of residence leads to an adult population with lower susceptibility (11% in the most recent serosurvey[63]). Consequently, cases often are seen in children and young adults. In a Florida outbreak, immunity to other flaviviruses (mainly from previous dengue infection) was also shown to protect against the acquisition of SLE.[7]

Cases of SLE have been reported in tropical America (Jamaica, Suriname, French Guiana, northern Argentina, and Brazil).[1,20,72] Increasing seroprevalence rates observed with increasing age indicates a higher frequency of endemic infection than is clinically apparent.[1,73] SLE is an emerging cause of arboviral disease in South America

and has been responsible for both sporadic cases and several outbreaks.[20,50,72] These sporadic SLE outbreaks principally have resulted in mild febrile illnesses that have been clinically confused with dengue. The largest outbreak reported to date occurred in 2005 in Cordoba, Argentina and resulted in 47 laboratory-confirmed or probable cases, 11 of which occurred in children. Nine adults died in this outbreak.[73]

CLINICAL MANIFESTATIONS

Clinical manifestations range from a mild influenza-like illness to fatal encephalitis.[8,60,66,84] A case definition that stratifies cases into clinical syndromes of encephalitis, aseptic meningitis, and febrile headache[8] (Table 175A-1) has proved useful in surveillance (Fig. 175A-5). Although children as a group exhibit milder symptoms, encephalitis develops in more than half of confirmed and presumptive pediatric cases, and 95 percent have objective clinical signs of CNS infection.[5,6,73,84]

SLE cannot be easily differentiated from other viral CNS infections on the basis of clinical features. Photophobia, headache, fever, nausea, vomiting, malaise, and neck stiffness are typical early symptoms. In approximately half of reported cases, an abrupt onset of weakness, incoordination, disturbed sensorium, or other neurologic signs may occur; but equally often, patients have nonspecific symptoms with subtle changes in coordination or mentation during a prodromal phase lasting several days to more than a week. Seizures have been reported in a third of adult cases.[80]

In addition to fever of abrupt onset and signs of meningeal irritation, patients nearly uniformly exhibit alterations in state of consciousness, such as restlessness, confusion, lethargy, delirium, or coma. Neurologic examination usually reveals general weakness, hyperreflexia, and tremulousness, but focal deficits are unusual findings. Cranial nerve palsies, especially those involving nerves VII, IX, and X, occur in 10 to 25 percent of cases.[8] Clinical signs of increased intracranial pressure have been reported in a few patients. Unusual localizing neurologic signs have been described in patients with involvement of the midbrain, thalamus, or brain stem. In a 4-year-old girl, paralysis of upward gaze was associated with a brain stem infection.[31] A 14-year-old boy with acquired parkinsonism attributed to SLE infection has been reported.[59] Ataxia has been observed in a fourth of the cases in children, and opsoclonus has been reported in several cases in young adults.[22,23,80] In a series of 26 children with SLE, seizures were observed in 8, 6 of whom had focal seizures; however, enteroviruses were isolated concurrently from the stool in 5 of the 8 patients.[5,57] It is not known whether they had enteroviral CNS infection. A confirmed case of SLE causing a seizure has been reported in a neonate.[83] In most cases, the fever abates 4 to 7 days after onset, and clinical improvement is evident early in the second week of illness. Polyradiculopathy and transverse myelitis have been reported.[8,68]

The peripheral leukocyte count is elevated modestly, with a shift to the left in most patients. Cerebrospinal fluid (CSF) usually contains fewer than 100 leukocytes/mm^3, with a median value between 100 and 200. However, in some cases, fewer than 10 cells and occasionally no cells are discovered in the CSF. An increasing ratio of mononuclear to polymorphonuclear cells is observed on successive examinations. CSF protein rarely exceeds 200 mg/dL, and hypoglycorrhachia is unusual.[8]

TABLE 175A-1 Definitions of Clinical Syndromes Caused by St. Louis Encephalitis

Encephalitis* (including meningoencephalitis and encephalomyelitis)
Acute febrile illness (oral temperature ≥37.8°C (≥100°F)
One or more signs in either of the following categories:
Altered level of consciousness (i.e., confusion, disorientation, delirium, lethargy, stupor, coma)
Objective signs of neurologic dysfunction (i.e., seizure, cranial nerve palsy, dysarthria, rigidity, paresis, paralysis, abnormal reflexes, tremor)
Aseptic meningitis*
Acute febrile illness
Signs of meningeal irritation (i.e., stiff neck with or without Kernig or Brudzinski sign)
No objective signs of neurologic dysfunction
Febrile headache*
Acute febrile illness
Headache (also may have other systemic symptoms, such as nausea or vomiting)
No signs of meningeal irritation or neurologic dysfunction

Modified from Brinker KR, Monath TP. The acute disease. In: Monath TP, editor. *St. Louis encephalitis.* Washington, DC: American Public Health Association; 1980, p 503-534.
*Cerebrospinal fluid pleocytosis is present in patients with encephalitis and aseptic meningitis; it also may be found in patients with the syndrome of febrile headache.

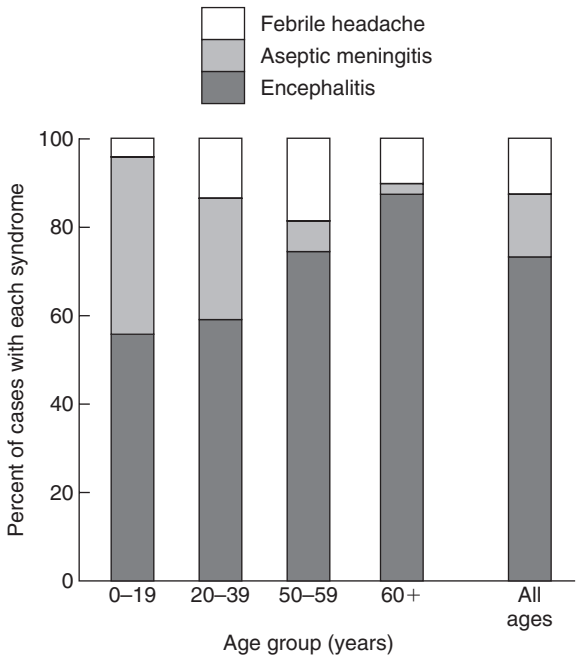

FIGURE 175A-5 ■ Distribution of St. Louis encephalitis cases by clinical syndrome and age. Although mortality rates and disease severity increase with age, most cases in children are clinical encephalitis. (Data from Zweighaft RM, Rasmussen C, Brolnitsky O, et al. St. Louis encephalitis: the Chicago experience. *Am J Trop Med Hyg* 1979;**28**:114-118.)

In one series, elevated serum aldolase levels suggested a myopathic process, and muscle biopsy and electromyography disclosed lower motor neuron dysfunction, possibly from spinal root involvement. Moderate transaminase elevations have been reported in 19 to 48 percent of adult patients. Decreased serum osmolality attributed to inappropriate secretion of antidiuretic hormone was observed in a fourth to a third of cases in two series.[8,9]

Urinary incontinence, frequency, or retention and pyuria or proteinuria have been reported in adult patients, and viral antigen was detected on cells in the urinary sediment by immunofluorescence in one report.[38] Lower motor neuron lesions may have been the mechanism for bladder symptoms in some patients.

Electroencephalographic abnormalities have included focal discharges, including periodic lateralized epileptiform discharges, but more consistently show diffuse generalized slowing.[5,9,80] Computed tomography scans may be normal, but magnetic resonance images have disclosed T2-weighted hyperintense abnormalities in the substantia nigra, consistent with edema.[14]

PATHOLOGY

Pathologic changes are found predominantly in the midbrain, thalamus, and brain stem but also in the cerebral cortex and cerebellum. Lesions are observed in the spinal cord in some cases.[65,71,75] The leptomeninges are affected to a variable degree with edema, small hemorrhages, and round-cell infiltration.

Perivascular and parenchymal inflammation is prevalent in the brain nuclei and scattered in the white matter of the brain stem and spinal cord and subcortical and deep cerebral areas. Nodular collections of inflammatory cells composed of lymphocytes, microglial cells, and monocytes are found in proximity to or surrounding degenerating neurons characterized by eccentric nuclear displacement, nuclear pyknosis, and cellular contraction. Vascular infiltrations and thrombosis have not been described, as they have in western equine encephalitis (WEE) and eastern equine encephalomyelitis (EEE). Focal demyelination, which is observed in WEE, has not been characteristic of SLE. Transmission electron microscopy may provide a pathologic diagnosis on tiny tissue fragments.[16]

PATHOGENESIS

After infection, viral replication occurs locally and in regional lymph nodes. After this eclipse phase, bloodborne (viremic) dissemination ensues, with secondary sites of replication occurring in muscle, endocrine, lymphoreticular, and other tissues and, in less than 1 percent of infections, in the CNS. Vascular endothelial cells may have a role in actively transporting virus from the capillary lumen to the brain and in supporting secondary viral replication.[21] Conditions that compromise cerebrovascular integrity and disrupt the blood-brain barrier may predispose to neuroinvasion; for example, concurrent CNS cysticercosis may be a risk factor for acquiring Japanese encephalitis, a related flaviviral infection. Although some experimental studies suggest that CNS invasion occurs through the olfactory epithelium, pathologic studies of Japanese encephalitis cases indicate widespread involvement of the brain stem, deep nuclei, and cortex, most consistent with hematogenous infection.

Recovery from flaviviral encephalitis depends on early intrathecal synthesis of antibodies and viral clearance by macrophages. The inflammatory response in related CNS infections consists of helper-inducer T cells and, to a lesser degree, B lymphocytes infiltrating the perivascular space and parenchyma from the blood. Macrophages and activated microglial cells in the perivascular space and parenchyma, respectively, are responsible for viral clearance. Outcome is determined by the comparative rates of viral spread and neuronal infection, the migration of inflammatory cells into the CNS, and the rapidity of the antibody response. Production of interferon is elicited in the brain of human SLE patients, but its role in limiting the spread of virus in the CNS is unclear.[39] The clinical course of SLE in HIV-infected persons has not been significantly different from that of other cases; however, few patients have been studied.

Resistance and susceptibility to some flaviviral infections in mice have been linked to genes associated with permissiveness to infection and the immune response. Environmental factors that influence susceptibility to flaviviral infection in experimental models include stress from cold or isolation, reticuloendothelial cell blockade, and heavy metal intoxication.

DIAGNOSIS

A laboratory diagnosis of SLE usually is made serologically, although virus rarely has been recovered from blood in the acute phase of illness.[35] Virus can be sought from brain and other organs obtained by biopsy or at autopsy by inoculation of Vero cell cultures and suckling mice intracerebrally.[33] Viral antigen has been demonstrated in brain sections and in urinary cell sediment.[33,64] It should be borne in mind that the clinical sensitivity of nucleic acid amplification tests (NAAT) is greater than that of antigen detection and viral culture using cell culture or suckling mouse inoculation.[33] The ultimate sensitivity of NAATs depends on the dynamics of viral replication and host tropism.

Serologic studies comparing antibody titers in paired specimens collected during the first week illness and 2 to 3 weeks later are considered the most appropriate for establishing the diagnosis.[33] Hemagglutination-inhibition, complement-fixation, and neutralizing antibody assays are used primarily in reference laboratories. A single immunoglobulin (Ig)M assay may be sufficient to establish the diagnosis in many cases. SLE-specific IgM capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic screening procedure.[33,49] Both serum and CSF samples should be tested. Intrathecal production of virus-specific IgM reflects recent infection because virus-specific IgM can be detected in serum or CSF in 75 percent or more of specimens obtained within 4 days of onset. In most patients, IgM levels decline in the convalescent sample and disappear approximately 4 months after onset, although IgM persisted at high

titer in a few patients for 6 months.[79] In areas where SLE is endemic, virus-specific IgM carried over from the previous transmission season could potentially lead to an erroneous diagnosis. The indirect immunofluorescent antibody procedure offers a similar capacity for rapid diagnosis; however, it is less sensitive than ELISA and IgM rheumatoid factor can lead to a false-positive result. Differentiation of antibody responses to West Nile virus, particularly during simultaneous outbreaks of the infections, has been aided by development of a duplex immunoassay.[29,41]

The serologic response in a primary flavivirus infection is usually type specific, but repeated infections lead to broad heterologous responses that are often difficult to interpret. Human infections with indigenous flaviviruses (e.g., Rio Bravo and Powassan) other than SLE are rare occurrences; however, in patients with antecedent yellow fever immunization or infection with dengue virus acquired in areas of the United States where dengue was previously endemic and recently reemergent (e.g., Texas and Florida) or acquired during travel or residence abroad, a broadly reactive flavivirus antibody response may obfuscate the diagnosis. Recent immigrants with preexisting dengue antibodies are the most common source of flaviviral antibodies in most areas of the United States.

DIFFERENTIAL DIAGNOSIS

In an endemic setting, clinicians should consider SLE principally in the differential diagnosis of patients with aseptic meningitis or acute encephalitis. However, in the context of an outbreak, the diagnostic threshold should be lowered to include patients with less specific findings, especially acute febrile illnesses with headache, and patients who exhibit confusion or are encephalopathic without fever. Increased suspicion of SLE in mildly ill patients should be directed particularly at children and young adults, in whom the infection often is manifested without meningoencephalitis. As mentioned earlier, in South America, SLE is a sporadic cause of acute febrile illness that, as a syndrome, has many non–vector-borne as well as vector-borne causes, including dengue.[40,76]

The clinical findings of SLE cannot be easily distinguished from those of other CNS infections. However, focal neurologic deficits are less characteristic of SLE and should suggest other diagnoses.[51] The combination of global confusion and tremulousness in SLE may suggest a metabolic encephalopathy, and in elderly patients, the initial manifestations of SLE can overlap the signs and symptoms of a cerebrovascular accident.

West Nile encephalitis and SLE are virtually identical in their clinical findings, their predilection for the elderly, and other epidemiologic features, including late summer seasonality, urban locus of epidemic transmission, and similar *Culex*-bird transmission cycles, such that individual cases cannot be differentiated except by specific laboratory testing.[29,41,43] In Brazil, Rocio virus, an antigenically related mosquito-borne flavivirus that was the cause of a single acute encephalitis outbreak in 1976, must be excluded, particularly because ELISA and other serological assays may cross react (see the discussion on other flaviviruses).

The progression of symptoms and localizing signs associated with herpes simplex viral encephalitis contrasts sharply with the clinical findings in SLE, in which localizing signs are less often demonstrated. Enteroviral infections have an overlapping summer seasonality but often are associated with clustering of illnesses in families and other epidemiologic clues of person-to-person spread. Skin eruptions, respiratory symptoms, pericarditis, myocarditis, and conjunctivitis are helpful distinguishing characteristics. Concurrent enterovirus infection and SLE may be associated with an increased risk for seizures during the acute phase of illness.[5,57] Enteroviral infections can be confirmed by detecting viral genomic sequences in CSF or blood by polymerase chain reaction or by recovery of virus from CSF or blood. Primary HIV, human herpesvirus 6, and mumps virus infections are other common infections that should be entertained in the differential diagnosis. A third of patients with mumps encephalitis do not have associated parotid gland swelling.

Adenoviral encephalitis is a rare infection in children, more severe than SLE, and sometimes associated with hepatic and other extraneural sites of infection. The presence of lymphoreticular involvement and typical hematologic features should suggest the clinical diagnosis of Epstein-Barr virus infection. Rabies virus encephalitis should be considered if the clinical picture is one of a progressive encephalitis.

Partially treated bacterial meningitis and parameningeal pyogenic infections are the principal bacterial causes to exclude. Cat-scratch fever can manifest as fever and encephalopathy mimicking arboviral encephalitis.[54] Seizures associated with *Shigella* enteritis and ataxia associated with typhoid fever potentially could be interpreted as a primary CNS infection. Tuberculous meningitis is typically a subacute illness; evidence of active extraneural sites of infection should be sought. A low CSF glucose level is a clue to the diagnosis.

In urban areas or where parental occupational exposure may occur, lead intoxication remains an important potential cause of encephalopathy in summer. Hyperthermia associated with sustained exposure to elevated environmental temperature likewise may lead to encephalopathy with seizures, signs of raised intracranial pressure, and evidence of hepatic dysfunction. This constellation of symptoms also may suggest Reye syndrome, although this disease typically occurs in the winter and spring after a respiratory viral infection, in particular influenza virus, and is characterized by hypoglycemia and an elevated blood ammonia level. Patients with salicylism exhibit similar clinical findings, but a history of salicylate ingestion, an elevated anion gap early in the course of illness, and an elevated blood salicylate level should suggest that diagnosis.

TREATMENT

Supportive therapy, as outlined in the earlier sections, should be aimed at maintaining cardiorespiratory function and fluid and electrolyte balance, controlling seizures,

and monitoring and maintaining normal intracranial pressure.[43] No specific antiviral therapy is available.

PROGNOSIS

The principal risk factor for a fatal outcome is advanced age (see Fig. 175A-5).* Among all cases reported to the Centers for Disease Control and Prevention from 1955 to 1971, as well as recent data from 2003 to 2007, 8 percent died, but the age-specific mortality rate in persons 60 years of age or older was 19.5 percent. Fatality rates as high as 38 to 80 percent were recorded in the 1933 St. Louis outbreak in patients who were 60 to 89 years of age. Mortality rates in children have ranged from 2 to 5 percent, with the highest risk in children younger than 5 years of age. The overall case-fatality rate in an outbreak in Hermosillo, Mexico (involving principally children), was 20 percent.[17] The high fatality rate in this instance is anomalous because fatality rates are usually lower in *C. tarsalis*–borne SLE outbreaks in the West.

In adults, coma, a low CSF leukocyte count (<100 cells/mm^3), and underlying hypertensive vascular disease have been factors associated with a fatal outcome.[10] Risk factors for mortality in children have not been described.

Recovery from SLE usually is complete or associated with soft sequelae such as emotional disturbances, dizziness, headache, memory impairment, and tremor.[3,25,27,52] In one study of 193 cases, 25 percent of children who were 1 to 4 years of age at the time of infection had serious neurologic sequelae, the highest rate of any age group.[56] The incidence of sequelae was 10 percent in children aged 5 to 9 years. Children who were younger than 1 year of age at the time of infection appeared to be spared any serious sequelae. Deficits in motor and intellectual function were reported in some cases. Seizures were not a significant residual abnormality. The same cohort monitored at intervals of 6 months to 14 years had no perceptible residual differences in intelligence quotient in contrast to the normal population. In a case report, persistent ataxia of the extremities and trunk and dysarthria were reported as residual findings in a 54-year-old patient secondary to postinfectious encephalomyelitis temporally associated with SLE.[29,69]

No deleterious effects of SLE on the outcome of pregnancy have been reported. However, infection with Japanese encephalitis virus in the second trimester resulted in transplacental viral transmission and abortion, whereas infection in the third trimester was not associated with fetal damage. In experimentally infected mice, vertical transmission led to learning deficits in congenitally infected pups.[2]

PREVENTION

Preventive public health efforts have focused on surveillance of viral activity in the enzootic cycle to predict epidemic activity. In many east central states, weekly serologic surveys of captured wild birds and sentinel chickens are conducted to detect rising seroprevalence rates that reflect viral amplification[47] and an increased risk for human infection. The abundance of female vector mosquitoes and increased viral infection rates in vectors also have been correlated with a risk for epidemic transmission.[82]

When viral activity is elevated, ground and aerial application of insecticides is aimed at reducing the infected adult vector population. If insecticides are applied early enough, viral amplification can be potentially attenuated and epidemic transmission aborted.

Avoidance of outdoor activity during the twilight and evening hours, use of repellents appropriately, and repair of screens or installation of air conditioners in residences are simple but effective measures that reduce exposure to adult mosquitoes. Improvement of drainage and removal of containers that could serve as mosquito breeding sites are important steps in preventing the disease.

A vaccine is not available, nor is vaccination of the general public a realistic preventive measure because of low attack rates and the intermittent and focal nature of outbreaks. However, if a vaccine or chemoprophylactic agent were available, selective administration to a targeted population, particularly the elderly, might be appropriate in an outbreak.

175B ■ WEST NILE VIRUS

José R. Romero

HISTORY

West Nile virus (WNV) was isolated first from the blood of a 37-year-old African woman in December 1937 in Omongo, West Nile district, in the Northern Province of Uganda while researchers were attempting to isolate yellow fever virus.[188] In the same report, these investigators demonstrated that sera from patients recovering from Japanese encephalitis virus could neutralize WNV. Shortly thereafter, this finding was confirmed and expanded to document that WNV was antigenically related not only to Japanese encephalitis virus but also to St. Louis encephalitis virus.[186]

In 1950, Melnick and coworkers[130] isolated WNV from the blood of three healthy children in Egypt, thereby demonstrating that WNV was not confined to a single geographic location. Before 1999, WNV was known to be endemic to Africa, the Middle East, Europe, west and central Asia, and Oceania. With its incursion into the United States in 1999[8,144] and subsequent spread throughout North America, Central America, and the Caribbean,[54,106,163] WNV has established a worldwide distribution.

The first reports of WNV as a cause of outbreaks of febrile illness came from Israel in the early 1950s and ultimately led to its being associated with a clinical entity coined West Nile fever.[18,72] Studies performed by Taylor and colleagues[194] at the U.S. Naval Medical Research Unit in Egypt in the early 1950s provided information about the epidemiology of WNV infection and clinical picture of West Nile fever in children. This information was augmented by the seminal report by Marberg and colleagues[125] describing the clinical characteristics of serologically and virologically confirmed cases of West Nile fever among adolescent and young adult military personnel during a 1953 epidemic in Israel. Sporadic reports of central nervous system (CNS) complications associated with WNV infection followed closely after the early clinical descriptions of West Nile fever and pointed to the neuropathogenic potential of WNV.* Further characterization of West Nile neuroinvasive disease (encephalitis, meningitis, acute flaccid paralysis) followed as additional outbreaks of WNV were reported.

During the past half century, outbreaks of WNV have occurred worldwide. Notable human outbreaks include Israel, 1951 to 1954, 1957, and 2000; France, 1962; South Africa, 1974; Algeria, 1994; Tunisia, 1997; Romania, 1996; and Russia, 1999.† Two of the largest epidemics recorded occurred in South Africa in 1974 and the United States in 2003. During the former, an estimated 18,000 cases of West Nile fever occurred.[54,81]

After the introduction of WNV into the North American continent in 1999, cases of West Nile fever and neuroinvasive disease remained at relatively low levels through 2001 and exploded in 2002 and 2003 when 4156 and 9862 cases, respectively, of WNV infection were reported to the Centers for Disease Control and Prevention (CDC)[32] The 2002 epidemic of WNV in the United States resulted in the largest epidemic of neuroinvasive West Nile disease ever recorded, with nearly 3000 cases reported.[150] Currently, WNV has superseded all autochthonous North American arboviruses as the single most important cause of arboviral disease in the United States.[44] The magnitude of the number of WNV infections is exemplified by an estimate, based on 2003 national blood donor screening data for WNV infection, that 735,000 cases of WNV infection occurred that year.[25]

VIROLOGY

WNV is a member of the Flaviviridae family of RNA viruses.[119] The viral family is composed of three genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*. WNV is a member of the *Flavivirus* genus and falls within the Japanese encephalitis virus serocomplex, along with Cacipacore, Japanese encephalitis, Kunjin, Murray Valley encephalitis, St. Louis encephalitis, Usutu, and Yaoundé viruses. Kunjin virus, which is endemic to Australia and Asia, is a subtype of WNV. Members within the Japanese encephalitis virus serogroup are antigenically related to each other.

WNV is a spherical, enveloped virus measuring approximately 50 nm in diameter. The viral envelope is derived from the lipid bilayer of the host cell and surrounds the approximately 25-nm nucleocapsid core of the virion. The host cell–derived envelope is modified by the insertion of two viral proteins: E (envelope protein) and M (membrane protein).

The genome of WNV is a single-stranded, positive-sense (messenger sense) RNA molecule measuring 11,029 nucleotides in length (Fig. 175B-1).[112,119] Two noncoding regions (5′ and 3′) flank the 10,302-nucleotide viral single open reading frame and measure 96 and 631 nucleotides, respectively. The open reading frame is organized as 5′-C-prM-E-NS1-NS2A-NS3-NS4A-NS4B-NS5-3′ and is transcribed into a single polyprotein of 3434 amino acids encoding three structural and seven nonstructural proteins.[112,119] The N-terminal portion of the polyprotein consists of viral structural proteins, whereas the remainder of the protein contains the nonstructural (NS) proteins. The viral polyprotein is cotranslationally and posttranslationally processed by host proteases and the viral protease NS2B-NS3 to yield three structural (i.e., E, prM, and C) and seven NS (i.e., 1, 2A, 2B, 3, 4A, 4B, and 5) proteins.

Viral attachment, endocytosis, membrane fusion, and viral assembly are mediated by the E protein. The search

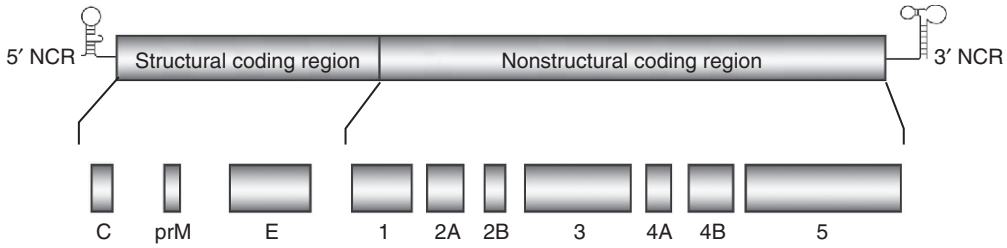

FIGURE 175B-1 ■ Organization and protein products of the West Nile genome.

for the cellular receptors of WNV has identified the integrin $\alpha_v\beta_3$ and the lectins DC-SIGNR and DC-SIGN as capable of binding WNV in vitro.[47,55] However, whether they are physiologically relevant in vivo remains to be documented. Once bound to its receptor, WNV gains entry into the cell through endocytosis; after a pH-dependent change occurs in the conformation of the E protein, the viral and host endosomal membranes fuse. The viral nucleocapsid is then released into the cytoplasm of the cell. Viral replication is thought to occur on the membrane of the rough endoplasmic reticulum. The C or capsid protein binds to the viral RNA genome and forms a ribonucleoprotein complex required for packaging of the genome.[139] The immature virions are assembled, accumulate in vesicles, and bud into the endoplasmic reticulum. The immature virions are processed as they traverse the secretory pathway. Immature viral particles contain a premembrane (prM) protein that blocks premature viral fusion by the E protein. The prM protein is cleaved to the M protein by the trans-Golgi protein furin during the egress of the mature virion from the secretory pathway. Virions are transported to the cell membrane in vesicles and ultimately released through exocytosis or budding.

The NS proteins regulate viral transcription and translation, as well as attenuate host immune responses to WNV.[119,173] The NS1 protein serves as a cofactor for the viral replicase and modulates the host innate immune response by inhibition of TLR3 signal transduction.[210] Host interferon (IFN) responses are inhibited by NS2A through inhibition of IFN-β promoter activity. This protein also may play a role in viral assembly. The NS3 protein is a serine protease and requires NS2B as a cofactor for activity. It also possesses NTPase and helicase activities. NS proteins 4A and B modulate IFN signaling. The NS5 functions as the RNA-dependent RNA polymerase and a methyltransferase. The NS5 protein from the virulent WNV strain NY99 is an antagonist of type 1 IFN-mediated JAK-STAT signal transduction.[113]

Phylogenetic analysis of WNV isolates from around the world has demonstrated the existence of up to seven lineages.[112,157] Lineages 1 and 2 constitute the major lineages. Strains that comprise lineage 2 are found exclusively in sub-Saharan Africa and Madagascar. In contrast, lineage 1 strains are found in geographically dispersed regions around the world and can be subdivided into three clades.[112] WNV strains from Africa, Europe, the United States, the Middle East, and Russia cluster within clade 1a. Kunjin virus and India WNV strains form clades 1b and 1c, respectively. WNV strains isolated from birds and a human during the 1999 outbreak in the United States and a WNV strain isolated in 1998 from a dead goose in Israel have been shown to be closely related.[111] Phylogenetic analysis of the prM protein and E glycoprotein demonstrated that they share more than 99.8 percent nucleotide homology, indicating that the North American strain of WNV almost certainly originated in the Middle East. Analysis of U.S. WNV isolates has demonstrated a slowly evolving nucleotide divergence. The initial WNV strain in the United States, NY99, was displaced in less than 4 years by the current dominant genotype WN02.

Genetic correlations appear to exist between genotype/lineage and virulence/fitness phenotype.[90,112,157] Viruses from lineage 1 have been associated with outbreaks of West Nile neuroinvasive disease, whereas those from lineage 2 appear to cause only asymptomatic infection or West Nile fever. Neurovirulence data by use of a murine model corroborate this finding, indicating that lineage 1 strains of WNV are more neuroinvasive than are those of lineage 2.[14] Nucleotide changes in the 3′ noncoding region and amino acid substitutions in the nonstructural and envelope proteins have been associated with increased morbidity and viral load in American crows, decreased incubation time for infection until transmission of WNV by *Culex pipiens* mosquitos, and modification of the host IFN signaling cascade. These changes have given rise to attenuated genotypes of WNV as it has spread across the United States.

EPIDEMIOLOGY

In temperate climates, WNV infections occur seasonally during the summer months, coinciding with periods of increased activity of its mosquito vectors. The peak period of activity for transmission of WNV to humans in the United States, Europe, and the Mediterranean basin generally is from July through October.[150,212] However, as WNV has spread southward in the United States, the period of reported transmissions has increased, with human cases being reported as early as April and as late as December.[84] Year-round transmission may be possible in tropical climates.

Infections of humans (i.e., epizootic infection) by WNV are incidental to its enzootic life cycle and, with rare exception, result in a "dead-end" infection without subsequent human-to-human transmission. Epizootic transmission of WNV occurs when sufficient numbers of mosquitoes that bite both birds and humans become

infected to allow transmission to humans. Important risk factors for the acquisition of human WNV infection are the amount of time spent outdoors when mosquitoes are biting; the presence of dead birds in the neighborhood; the exposure to mosquitoes; and the land cover, water, and soil suitable for harboring potentially infected mosquitoes.[24,48,80,138] Marked increases in WNV infections have been associated with economic factors, such as the downturn in the housing market and delinquent mortgages, which has led to large numbers of neglected residential swimming pools in some areas.[166]

The enzootic cycle of the WNV requires replicative phases in its mosquito vectors and avian (or other) hosts. After WNV-infected blood meal has been ingested, the virus penetrates the mosquito's gut.[70] Viral replication then takes place in the salivary glands and nervous system of the mosquito. In mosquito tissues, WNV is nonlytic and results in persistent infection for the lifetime of the vector.

Mosquitoes play an important role in transgenerational and transseasonal maintenance of the WNV enzootic cycle. Laboratory and field observations had documented that female *C. pipiens* mosquitoes can transmit WNV vertically to F1 progeny.[60,199] In addition, WNV can survive the winter by overwintering in hibernating female mosquitoes, as documented with *C. pipiens*, which thereby serve as a source of WNV to initiate the enzootic cycle the following spring.[143]

Although numerous mosquito species have been found to be infected with WNV, ornithophilic members in the *Culex* genus are the principal vectors for the transmission of WNV around the world. These include *C. pipens* and *Culex quinquefasciatus* in Europe, *Culex perexiguus* in North Africa and the Middle East, *Culex univittatus* in sub-Saharan Africa, *Culex tritaeniorhynchus* in south Asia, *Culex annulirostris* in Australia, and species of the *Culex vishnu* complex in India.[105]

Although WNV has been found in 59 of the 173 North American species of mosquitoes, only about a half-dozen are considered to be important vectors for transmission to humans.[84] As in other regions of the world, *Culex* spp. of mosquitoes are important vectors[84]; *C. pipens* (the northern house mosquito) and *C. quinquefasciatus* (the southern house mosquito) are considered to be the predominant vectors in the northeast, southern, and southwestern United States, respectively. *Culex tarsalis* is a predominant vector west of the Mississippi River. *Culex nigripalpus* and *Culex salinarius* may be important vectors in regions where they are abundant. Last, *Culex restuans* also has been found to be a significant contributor to WNV-positive mosquito pools. Although arthropods can be infected with WNV, they are not thought to be important in transmission of WNV.

Birds are thought to be the principal amplifying hosts for WNV. Nearly 200 species of North American birds are susceptible to infection by WNV.[105] However, only birds capable of sustaining high-titer viremia for significant periods are capable of infecting the mosquitoes that feed on them. In vivo experiments using *C. tarsalis* have shown that 74 to 100 percent of mosquitoes consuming blood meals containing $10^{7.1}$ plaque-forming units (PFUs) per milliliter become infected. In contrast, 36 percent or fewer mosquitoes become infected after the consumption of blood containing $10^{4.9}$ PFU/mL.[73] As a point of comparison, on the basis of blood tested from viremic blood donors, the maximum viral load in human blood is approximately $10^{3.2}$ PFU/mL.[84] This finding would indicate that humans fail to produce blood viral titers of sufficient magnitude to infect mosquitoes. Most mammals also fail to have sufficient levels of viremia to permit transmission to mosquitoes.

Songbirds (Passeriformes), shorebirds (Charadriiformes), owls (Stringiformes), and hawks (Falconiformes) develop adequate viremia to infect mosquitoes feeding on them (pigeons and ducks do not). House finches, house sparrows, common grackles, and, in particular, corvids such as crows, magpies, and jays have been shown to be highly infectious to mosquitoes.[84,105] In addition, they have a high mortality rate after acquiring infection with WNV. Die-offs of avian species serve as epidemiologic markers for WNV activity in the environment.[75,138]

Unlike mammals, some amphibians appear to be capable of sustaining levels of viremia that potentially could be sufficient to infect mosquitoes and may serve as competent reservoirs for their infection. In the United States, alligators *(Alligator mississippiensis)* infected with WNV produced sufficient viral loads to infect mosquitoes.[104] Detection of WNV RNA in mosquitoes, alligators, and alligator-derived blood meals collected at alligator farms in Louisiana support the role of alligators as competent hosts for WNV amplification and transmission.[198] In Russia, the lake frog *(Rana ridibunda)* may be a host for WNV.[84,107]

In areas where WNV traditionally has been endemic, seroprevalence studies document that most individuals acquire WNV infection during childhood. Such early acquisition of WNV infection results in large portions of the adult population with serologic evidence of immunity to WNV and may attenuate the occurrence of large outbreaks of WNV infection. Studies conducted in the 1950s in Egypt documented that a rapid rise in the presence of antibodies occurred in children 1 to 4 years of age such that by the time children were 4 years of age, 50 to 80 percent had neutralizing or complement-fixing antibodies to WNV.[130,194] Similar patterns of acquisition of WNV-specific antibodies have been documented in the Sudan, Central Africa, and Nigeria.[188,194] Interestingly, more recent studies conducted in Egypt indicate that the seroprevalence rates in children and young adults, although still high, may be decreasing.[50,53] One can speculate that mosquito abatement programs and, possibly, changes in lifestyle have resulted in decreasing numbers of infections in children.

Seroepidemiologic studies conducted in areas where initial WNV has resulted in large outbreaks of West Nile fever and neuroinvasive disease document low seroprevalence rates among the general population.[124,137,140,196] Investigation of the seroprevalence of WNV infection after an outbreak of WNV in Romania after the first major WNV epidemic in Europe found it to be 4.6 percent.[196] After the initial North American outbreak of West Nile encephalitis in New York in 1999, the seroprevalence at the outbreak's epicenter was found to be approximately 2.6 percent.[137] Based on data derived from

the screening of the United States blood supply, the estimated prevalence of past WNV infection among the United States population is approximately 1 percent.[161] In areas where postepidemic seroprevalence has been conducted, it has been found to range from 2.6 to 14 percent; too low to protect against future large-scale outbreaks of WNV disease.[54,140,161]

Multiple novel, non–vector-borne modes of WNV transmission were identified during the North American epidemics. Transfusion-associated transmission of WNV was reported for the first time in 2002, when 23 cases were confirmed.[134,156] WNV virus infection has resulted from the transfusion of red blood cells, platelets, fresh frozen plasma, and granulocytes.[42,43,131,133,156] Of the 32 cases, 5 (16%) occurred in children younger than 18 years[42,133,156] Three of the children had immunocompromising conditions (i.e., acute myeloid leukemia, rhabdomyosarcoma, stem-cell transplant). The three children received platelet infusions and developed West Nile meningoencephalitis; all survived. The sole adolescent was a victim of a motor vehicle accident and received a transfusion of red blood cells. This patient subsequently became an organ donor and was implicated in four cases of transplantation-associated transmission of WNV.[36,94] A sole case of acquisition of WNV via granulocyte transfusion has been reported.[131]

As a result of transfusion-associated WNV transmission, national screening of blood donations for the presence of WNV by nucleic acid amplification–based testing was initiated in June 2003. Although active screening has identified 2557 presumably viremic blood doners, 11 probable or confirmed cases of transfusion-acquired WNV infection occurred through 2010 (none of which occurred in children); they most likely were attributable to donations containing very low levels of virus.[32,40,121,131,133]

In addition to transmission that occurs through transfusion of blood products, transmission through organ transplantation has been documented worldwide.[36,41,43,94,167] However, no cases in pediatric transplant patients have been reported.[121] The risk for acquiring West Nile neuroinvasive disease is approximately 40 times greater in organ transplant recipients than in the general population.[108] Unlike blood donations, organ donations currently are not required to be screened by nucleic acid amplification for WNV infection, nor is it performed routinely.

Confirmed or suspected maternal-fetal and maternal-infant vertical transmission of WNV has been reported.[4,35,34,83,149] In the most rigorously documented case,[4,34,83] confirmed maternal WNV infection occurred during the 27th week of gestation. The infant, delivered at 38 weeks of gestation, was found to have bilateral chorioretinitis, severe bilateral white matter loss in the temporal and occipital lobes, and tissue destruction in a temporal lobe. The presence of WNV-specific immunoglobulin (Ig)M was confirmed in cord blood, infant serum, and cerebrospinal fluid (CSF), although the CSF contained red blood cells. Maternal serum also contained WNV-specific IgM at the time of birth. The WNV genome was detected in the umbilical cord tissue and placenta by reverse-transcription polymerase chain reaction (RT-PCR). No WNV genome was detected in the infant's CSF.

Evaluation of 71 pregnancies reported to the Center for Disease Control and Prevention's (CDC's) WNV pregnancy registry failed to identify any confirmed cases of congenital WNV infection.[149] However, three infants who lacked evidence of anti-WNV IgM in cord blood or infant serum at the time of delivery subsequently were found to have serologic evidence of infection that may have been acquired congenitally. A breast-fed term infant, whose mother had onset of West Nile neuroinvasive disease 6 days before delivery, developed West Nile meningitis at 10 days of age. Another breast-fed infant, born to a woman with acute West Nile fever at the time of delivery, was noted to have a transient rash at birth. No serum or cord blood was available for testing. However, at 1 month of age, the infant was found to have WNV-specific IgM antibodies. In the final case, the infant's mother had a febrile illness 3 weeks before delivery. The infant appeared to be healthy at birth, but at 7 days of age developed seizures. Evaluation of the infant at 17 days of age found lissencephaly and West Nile encephalitis with WNV-specific IgM antibodies detectable in the CSF. Because two of the infants were breast-fed, the possibility exists that WNV was transmitted in that manner. In addition, in none of the cases could the possibility of mosquito-borne transmission of WNV be excluded conclusively. This report also failed to link WNV infection during pregnancy with an increased frequency of spontaneous abortion, premature birth, or low birth weight.

WNV has been detected in the breast milk of infected women.[35,149] At least one case of possible transmission of WNV associated with breast-feeding has been reported.[35,82,149] The mother received packed red blood cell transfusions on the first two postpartum days. Ten days post partum, the mother developed headache followed by fever. On evaluation, she was found to have CSF pleocytosis and the presence of WNV-specific IgM in the CSF. The infant was breast-fed for the first 17 days of life, and although the infant was clinically asymptomatic, a serum sample obtained at 25 days of age was found to have WNV-specific IgM. Because of the paucity of additional case reports, it appears that the risk for WNV transmission from mother to infant through breast-feeding is low. The current state of knowledge about transmission of WNV through breast milk does not warrant a change in breast-feeding recommendations.

Additional nontraditional modes of confirmed or possible transmission of WNV has been reported through laboratory exposure, animal autopsies, percutaneous injury, conjunctival inoculation, aerosol inhalation, and dialysis.[37-39,64,79,200,201]

With the exceptions of Alaska and Hawaii, every state in the United States has reported human, mosquito, avian, or animal WNV. From 1999 to 2011, 31,414 cases of WNV infection were reported to the CDC (Table 175B-1).[32] Neuroinvasive syndromes accounted for 13,241 cases (42.1%), and non-neuroinvasive syndromes were reported in 18,173 cases (57.9%). During the same period, 1282 deaths (4%) were reported.[32]

Data include cases reported as encephalitis, meningoencephalitis, meningitis, and/or acute flaccid paralysis with age data.
*Data show the incidence per 100,000 persons.
†Data include cases reported as acute flaccid paralysis only (not those reported as encephalitis or meningitis with acute flaccid paralysis). Data were only available from 2004 to 2007.
‡This includes data from 2004 to 2007 only.

Pediatric-specific epidemiologic and clinical data regarding WNV infections has become available.[82-84,121] However, it should be borne in mind that available data are most likely incomplete because of underreporting of cases. After an Ohio outbreak of WNV, the county-wide seroprevalence rate was found to be 1.9 percent. However, among children younger than 17 years, the seroprevalence rate was nearly 3.5 times higher: 6.4 percent.[124] From 1999 to 2007, 1478 cases of West Nile infection were reported to the CDC. For that period, the median annual incidence of West Nile neuroinvasive disease was 0.07 cases/100,000 children. By way of comparison, for the same period the median annual incidence for adults 18 to 49 years of age and adults older than 50 years was 4 times and 13 times higher, respectively (Table 175B-2). The five states with the highest state-level median annual pediatric incidences were South Dakota (1.02/100,000), Wyoming (0.82 cases/100,000), New Mexico (0.59/100,000), and Nebraska (0.45/100,000) (Fig. 175B-2). The Great Plains and mountain states had the highest cumulative incidences.[121]

The distribution of WNV syndromes among children has been difficult to define because of underreporting of pediatric cases of West Nile infection.[82] A recent report of pediatric cases from 1999 through 2007 provides the clearest picture of the disease in children (see Table 175B-2).[82,121] For that period, a total of 27,605 cases of West Nile infection were reported. During that same period, 1478 (5%) cases of West Nile infection in children younger than 18 years of age were reported. Pediatric cases were reported from 41 states. West Nile fever occurred in 1009 (68%) and neuroinvasive disease in 443 (30%). For 26 cases, disease was not specified. Children accounted for 4 percent of all cases of neuroinvasive disease. For those children with neuroinvasive disease, 208 (47%) had meningitis, 163 (37%) encephalitis or

†This includes data from 2004 to 2007 only.

meningoencephalitis, and 5 (1%) acute flaccid paralysis alone. It should be noted, however, that 2 patients each reported as having encephalitis and meningitis had associated acute flaccid paralysis. For 15 percent, the specific neuroinvasive syndrome was not specified.

The median age of the reported children with West Nile fever was 14 years (range, 1 day to 17 years). The median age of children with West Nile neuroinvasive disease was slightly younger, at 12 years (Table 175B-3).[121] The 78 percent of cases of West Nile fever and 63 percent of neuroinvasive disease occurred in children 10 years of age or older. Congenital infection appears to have occurred in two children. Only three deaths were reported—1-month-boy, a 14-year-old boy, and a 16-year-old girl. Two of the children who died of neuroinvasive disease had underlying medical conditions; one had an immunodeficiency and the other lissencephaly.[83,121,147]

Comparison of pediatric and adult cases of West Nile neuroinvasive disease from 1999 to 2007 demonstrated that adults 50 years of age and older more frequently had encephalitis or meningoencephalitis than did children or adults younger than 50 years.[121] The case-fatality rate among children was similar to that observed among adults younger than 50 years—0.6 and 1.3 percent, respectively. The fatality rate among adults 50 years of age and older was 14 percent.

Taken together, the available information indicates that WNV infection in children is typically mild, resulting in West Nile fever in more than two thirds of children with symptomatic infection. The distribution of West Nile neuroinvasive disease in children indicates that in individuals younger than 18 years, the predominant West Nile neuroinvasive syndrome is meningitis followed by encephalitis.

PATHOGENESIS

The pathogenesis of West Nile encephalitis has been explored in animal model systems. Subcutaneous inoculation of WNV is thought to result in WNV infection and replication in Langerhans dendritic cells.[26] Domain III of the WNV envelope (E) protein is believed to interact with DC-SIGN or DC-SIGNR to mediate cellular attachment. Under control of interleukin (IL)-1β, activated Langerhans cells migrate to regional lymph nodes and result in a primary viremia that develops after the virus reaches the systemic circulation through the

thoracic duct.[26] In mice, peak viremia occurs by the second day after infection and clears by the sixth day. Virus subsequently can be detected in spleen, brain, and spinal cord. Because of the simultaneous appearance of virus in the brain and spinal cord, a hematogenous route for the CNS infection has been postulated. In humans, WNV can be detected in the neurons of the cerebral cortex, thalamus, brain stem, basal ganglia, cerebellum, and spinal cord, primarily in the anterior horn. Similar locations have been seen in mice and hamsters. Infection of the neurons in these sites results in meningoencephalitis and acute flaccid paralysis. Several mechanisms have been postulated for the neuronal injury seen in WNV infection[183]: viral injury to infected neurons through apoptosis, targeting of infected neurons by cytotoxic T lymphocytes, and neuronal death as a result of bystander injury. Cell death of WNV-infected neurons has been shown to be caspase-3 dependant.

The mechanism by which WNV gains access to the CNS is not fully understood. WNV binding to Toll-like receptor (TLR)3 has been shown to result in TLR3 receptor–dependent inflammatory response with resultant production of tumor necrosis factor (TNF)-α and IL-6.[204] TNF-α may modulate the ability of WNV to invade the CNS, inducing breakdown of the blood-brain barrier. Macrophage migration inhibition factor, induced endothelial cell adhesion molecule (ICAM)-1 and matrix metalloproteinase 9 also have been shown to play roles in increased brain capillary epithelial permeability.[5,52,203] Additional postulated mechanisms through which WNV may breach the blood-brain barrier include infection or passive transport through the choroid plexus epithelial cells or the endothelium, infection of olfactory neurons, transport within infected immune cells that traffic into the CNS (Trojan horse mechanism), and retrograde axonal transport in infected peripheral neurons.[173]

Cessation of the viremia occurs by the sixth day in mice and is coincident with the appearance of type-specific antibody response. Viral clearance from all tissues is complete by 2 to 3 weeks after infection. Humoral immunity is essential to the recovery from WNV infection, as demonstrated by the uniform death of B cell–deficient mice.[59] B cell–deficient mice could be protected from lethal infection by the passive transfer of serum from infected and immune wild-type mice. Mice deficient in $CD4^+$ T cells exhibited prolonged detection of WNV in the CNS, lower WNV-specific levels of IgM and IgG, as well as uniform lethality, indicating that the principal protective role of these cells is to assist in antibody responses. γ/δ T cells that secrete IFN-γ may control viral replication through direct antiviral mechanisms and contribute to adaptive immune responses.[173]

Although clearance of WNV from the CNS and other tissues depends primarily on humoral immunity, cytotoxic T cells also play a role.[118,197] Increased mortality rates in association with higher and sustained WNV loads in the CNS and spleen were observed in mice deficient in $CD8^+$ T cells or class I major histocompatibility complex molecules.[182] In addition, control of WNV infection in the CNS requires IFN-α/β. IFN-α/β also may help increase the survival of neurons. Finally, chemokines such as CXCL10 and CCL5 and their ligands CXCR3 and CCR5 aid in the recruitment of $CD4^+$ and $CD8^+$ T cells and monocytes to the CNS.[173]

CLINICAL MANIFESTATIONS

Most WNV infections in children and adults result in subclinical disease. In general, WNV infection in children more frequently results in asymptomatic infection or milder disease than that in adults.* One report documented that children were 4.5 times more likely to become infected with WNV during an epidemic but 110 times less likely to develop neuroinvasive disease.[124] In another, the estimated incidence of neuroinvasive disease was 1.4/100,000 in children aged 5 to 17 years in contrast to 14.3/100,000 in individuals aged 18 years or older.[109] In adults, multiple reports have identified increasing age as the single most significant risk factor for the development of neuroinvasive disease, as well as adverse outcome.[121,141,158] The incidence of severe neurologic disease is 10 times higher in individuals aged 50 to 59 years and 43 times higher in persons aged 80 years or older in contrast to those 20 years of age or younger. Chronic illnesses, such as hypertension, diabetes mellitus, cardiovascular disease, and alcohol abuse, also have been identified as risk factors for severe disease.[20,141,144,158] These factors have not been linked to an increased risk for the development of severe disease in children.

In the early 1950s, therapeutic inoculation of WNV into patients with malignant neoplasms in advanced stages resulted in a high incidence of development of encephalitis among recipients and pointed to the role of immunosuppression as a risk factor for West Nile neuroinvasive disease.[190] This finding subsequently was substantiated by the recognition that transplant recipients were 40 times more likely to develop West Nile neuroinvasive disease.[108] Reports of West Nile neuroinvasive disease in immunocompromised children are consistent with immunosuppression as a risk factor in this population also.[6,65,88,165,191] Reports also have indicated that the use of immunomodulating agents such as infliximab, rituximab, methotrexate, and fludarabine may predispose to the development of severe WNV infection.[11,45,116,128]

Approximately 20 percent of infected adults develop West Nile fever. Because of the fever's mild nature, only about half of individuals with West Nile fever ever seek medical attention. WNV neuroinvasive syndromes (e.g., encephalitis, meningitis, meningoencephalitis, and acute flaccid paralysis) develop in less than 1 percent (1/140 to 320) of adults infected with WNV.† The occurrence of West Nile neuroinvasive disease in children is significantly less.[109,124] In one study, it was calculated to occur in approximately 1/4200 infected children.[124]

The incubation period of WNV infection ranges from 2 to 14 days but usually is 2 to 6 days.[27,72,105,125] Viremia may be present from approximately 2 days before to approximately 4 days after the onset of the illness.[71] In

*References 46, 72, 121, 144, 175, 192.
†References 137, 144, 158, 196.

immunosuppressed individuals, incubation periods up to 3 weeks have been reported and may exhibit prolonged periods of viremia.[94,156]

In children* and adults, West Nile fever is an influenza-like febrile illness characterized by an abrupt onset of fever that typically ranges from 38° to 40° C (100.4° to 104° F). It is accompanied by fatigue, malaise, anorexia, headache, myalgias, and weakness.[27,72,125,158,206] Ocular pain on eye movement has been reported.[72,125] A diffuse, nonpruritic, macular, papular, maculopapular or morbilliform exanthem and diffuse lymphadenopathy also may be seen. On occasion, it has been described as petechial.[22,49,169] The rash spares the palms and soles and generally involves the chest, back, and arms.[169] The exanthem may be present more frequently in children than in adults, regardless of the WNV syndrome, occurring in 50 percent.[23,49,169] The exanthem generally is present for less than a week. Neck pain and photosensitivity often are reported. Gastrointestinal complaints such as nausea, vomiting, abdominal pain, and diarrhea may occur. Sore throat and cough also have been reported. The illness generally is short-lived, lasting only 3 to 6 days.[72,92,125] Convalescence, however, may take many weeks and is characterized by fatigue.[72,125,206]

Other nonneurologic WNV syndromes that have been reported in adults include cardiac dysrhythmias, myocarditis, pancreatitis, hepatitis, rhabdomyolysis, myositis, and orchitis.† Myocarditis and hepatitis have been reported in children with West Nile infection.

Although cases of West Nile neuroinvasive disease have been reported in children,‡ most of the information about these clinical syndromes has been derived from reports that have involved predominantly adults.§ However, on the basis of a limited number of pediatric cases and series, the clinical presentation in children appears to parallel that of adults.[175] Although discussion of each of the neuroinvasive syndromes individually (i.e., meningitis, encephalitis, and acute flaccid paralysis) is convenient, one should recognize that patients may have components of each in their clinical presentation. Finally, the clinical findings in West Nile neuroinvasive disease in children and adults are not sufficiently distinct to distinguish them from those of other viral meningitides or encephalitides.

In adults, the onset of West Nile meningitis tends to be abrupt, with fever, headache, and neck stiffness and meningeal signs (Kernig and Brudzinski signs).¶ Photophobia and phonophobia may be present. The headache pain may be severe enough to warrant the use of opioid analgesics. Weakness frequently is reported.[49,65] Additional associated symptoms may include those seen with West Nile fever: gastrointestinal and respiratory symptoms (i.e., nausea, vomiting, diarrhea, sore throat, and cough), rash, and lymphadenopathy. Dyskinesias in the form of tremors, myoclonus, or parkinsonism also may occur.

The reported clinical findings of West Nile encephalitis in children* are similar to those described in adults.† The onset of frank encephalitis may be preceded by a brief period, or prodrome, of fever, headache, rash, and malaise consistent with West Nile fever. In some cases, the appearance of fever is coincident with the onset of mental status changes. The mental status changes may range from a mild confusional state to severe encephalopathy and coma. Generalized weakness is a common component of the clinical spectrum of encephalitis. Paresis or palsies may be present. Ataxia, dysmetria, tremors, myoclonus, and parkinsonism may be seen.[49,135,146] Signs of bulbar dysfunction, such as dysarthria, dysphagia, and respiratory failure, have been reported. If a component of meningitis is present (i.e., meningoencephalitis), signs and symptoms described before for meningitis also may be present. Seizures have been reported in children‡ and may be focal with associated neurologic signs similar to those of herpes simplex virus encephalitis.[168,202]

Acute flaccid paralysis in association with WNV infection was reported first in 1979[67] and may occur in the absence of meningitis or encephalitis. Several reports of acute flaccid paralysis, alone or in association with encephalitis, developing after the occurrence of WNV infection in children have been published.[22,65,76,86,171] The onset of the paralysis occurs early in the illness, usually within the first 72 hours.[176] Pain or paresthesia in the affected limb preceding the onset of weakness is reported in most cases.[76,176] Patients exhibit asymmetric weakness, hypotonia, and absent or diminished deep tendon reflexes. Pain or sensory function in the affected limbs remains intact.§ However, at least one report has documented electrophysiologic evidence of sensory fiber loss in association with severe spinal cord involvement.[61] It is postulated that this finding could be explained by damage to neurons in the dorsal root ganglia. Tremor, myoclonus, and parkinsonism are common findings.[177,179] In severe cases, changes in bowel and bladder function or quadriplegia may occur. Involvement of the brain stem motor nuclei of the vagus and glossopharyngeal nerves can result in dysphagia, dysarthria, and acute respiratory failure requiring assisted mechanical ventilation.[22] Patients with dysphagia and dysarthria are at greater risk for the development of respiratory failure.[176]

Ocular manifestations of WNV infection include chorioretinitis, vitritis, and uveitis.[9,175] Chorioretinitis has been described in congenital and postnatal WNV infections[4,9,175] and may be more common than is realized.[85] Postnatal cases of West Nile chorioretinitis have been reported solely in adults. The lesions are reported to cluster in the temporal and nasal regions of the peripheral retina and have been described as multifocal and "target-like." One suggestion is that the distribution and

appearance of the lesions are sufficiently distinct to be considered characteristic for WNV infection.[87] In the sole reported case of congenital WNV infection, the infant had a large chorioretinal scar involving the retina of the right eye. Mild chorioretinal scarring was observed in the far temporal periphery.[4,9] Vitritis also has been reported in children and can lead to blurring and loss of vision.[211]

Other rarely reported neurologic manifestations of West Nile neuroinvasive disease in adults include optic neuritis, myelitis, Guillain-Barré syndrome,[2] and polyradiculitis.[155]

Recently, the possibility of long-term persistence of West Nile virus infection has been raised.[142] WNV genome was detected by RT-PCR in the urine in 20 percent of cohort of patients with neuroinvasive disease 1.6 to 6.7 years after initial infection. All patients reported persistence of neurologic symptoms or signs. This finding is consistent with findings in the hamster model WNV infection and suggests ongoing replication in renal tissue. However, attempts to isolate virus from the urine were unsuccessful. In addition, a higher than expected prevalence of chronic kidney disease associated with proteinuria and hematuria has been documented in a cohort of patients with a history of neuroinvasive WNV.[148]

OUTCOME

Based on cases reported to the CDC from 1999 to 2007, the mortality rate in children is less than 1 percent.[121] Although reports of death in children as a result of WNV infection are rare,[31,69,82,88] WNV outbreaks associated with significant pediatric mortality rates (12.9%) have been documented.[58,114] From 2002 to 2011 the case-fatality rates in adults ranged from 2.6 to 6.8 percent (mean, 4.6%).[32] Hospitalized persons 75 years or older are nine times more likely to die than are younger patients. Other reported independent risk factors for death in adults are change in level of consciousness and anemia at presentation.[46] In addition to early mortality, delayed mortality, occurring years after infection, has been reported.[122]

Although complete recovery from West Nile fever is expected, it may take several weeks before children and adults return to preillness levels of health.[72,155] Watson and colleagues[207] found that the median time to complete recovery in adults was 60 days. Postillness fatigue was reported in 98 percent, and the median duration of fatigue was 36 days. Sixty-one percent of patients reported muscle weakness of a median duration of 28 days. Other symptoms that persisted for longer than 7 days were reported in more than half of the subjects and included headache, muscle pain and aches, difficulty concentrating, joint pain and aches, and sensitivity to light. Of those who worked or attended school, nearly 60 percent reported absenteeism of more than 7 days.

Neurologic outcome of children after West Nile neuroinvasive disease has not been assessed systematically. The published case reports of West Nile neuroinvasive disease in children are most likely biased by the disease severity or outcome and limited by a lack of long-term follow-up of patients. As such, reliable information about the outcome of West Nile encephalitis and acute flaccid paralysis is lacking. However, on the basis of the review of 45 reported cases of West Nile neuroinvasive disease in children and adolescents for whom clinical and outcome information was provided,* recovery from meningitis appears to be complete in children (N = 20). Among cases of encephalitis, meningoencephalitis, and acute flaccid paralysis (N = 25), approximately 50 percent of children were reported to have neurologic sequelae at the time of last medical encounter or at the time the report was submitted. The reported sequelae among children include seizures, weakness, paralysis, gait disturbances, motor difficulties, language and speech deficits, dysphagia, behavior problems, cognitive deficits, mental retardation, difficulty concentrating, difficulties with memory and comprehension, facial palsy, hypertonicity, and persistent vegetative state.†

Between 50 and 65 percent of individuals will have evidence of neuropsychiatric dysfunction at the time of discharge.[209] Longer term outcomes have been reported by Sejvar and colleagues.[178] Comparison of neurocognitive and quality-of-life outcomes of adults returning to independent living after hospitalization for West Nile fever, meningitis, and encephalitis to patients with chronic fatigue syndrome and a normative control group. Fifty percent of patients recovering from West Nile fever reported persistent symptoms, diminished quality of life, and functional impairment. In persons recovering from West Nile meningitis and encephalitis, 75 percent of individuals in each group reported the same. Twenty-two percent of recovering individuals had persistent WNV-associated neurologic dysfunction (i.e., focal weakness or movement disorders). Interestingly, overall, no significant differences in objective neurocognitive performance were observed among the three groups. However, it should be noted that for some neurocognitive subtests sensitive for visual processing, executive function, and maintenance of vigilance the WNV group performed below the 15th percentile in contrast to the normative control. Taken together, these findings indicate that most adults returning to independent living after hospitalization for the three major West Nile syndromes had persistent subjective complaints but had normal cognitive function. The reported sequelae of West Nile neuroinvasive disease in adults include fatigue, fever, weakness, difficulty concentrating, memory loss, depression, paresis, tremor, myoclonus, and parkinsonism.[27,30,209]

Patients recovering from West Nile acute flaccid paralysis exhibited persistent associated neurologic signs, poor physical recovery, and atrophy of affected limbs.[97,177] However, like patients with other WNV neuroinvasive syndromes, mental health outcomes are favorable.[97] Although the degree of initial paralysis was not correlated with long-term outcome in an early report,[28] a more recent publication indicates that the degree of initial paralysis may be an important indicator of long-term

*References 6, 22, 29, 46, 57, 65, 86, 88, 89, 109, 147, 191, 202, 208, 211.

†References 6, 22, 29, 65, 86, 89, 147, 191, 202, 208, 211.

outcome.[177] The greatest recovery in strength occurred during the first 4 months after paralysis.[177]

LABORATORY FINDINGS

As is the case with the clinical findings of WNV infections, routine laboratory studies are nonspecific and do not provide conclusive evidence about the etiologic agent. Similar to those in adults, hematologic findings in children include leukocytosis, leukopenia, normal total white cell count, and lymphopenia.* Pediatric and adult cases of encephalitis hyponatremia have been reported.[22,46,209] Elevations of transaminases and creatine kinase may be seen in children with hepatitis and myositis.[22,211]

Cytochemical evaluation of the CSF generally reveals an abnormal white cell count and protein concentration.† A predominantly lymphocytic pleocytosis with, generally, fewer than 200 cells/mm^3 is a frequent finding. Cell counts of more than 2000 cells/mm^3 have been reported. Early in the infection, the CSF may show a polymorphonuclear cellular predominance that later shifts to a lymphocytic pleocytosis.[51] A mildly increased protein concentration of less than 100 mg/dL generally is seen. However, considerable variation in CSF protein concentration has been reported in patients with West Nile encephalitis. A normal CSF glucose concentration generally is observed.

ELECTRODIAGNOSTIC STUDIES

Electrodiagnostic study findings are abnormal in most patients with West Nile encephalitis.‡ Electroencephalographic abnormalities have included diffuse irregular slow waves, focal sharp waves, and subclinical electrographic seizures. An anterior preponderance of slow waves has been suggested as characteristic of West Nile encephalitis.[68] Reports of focal electroencephalographic findings suggestive of herpes simplex virus encephalitis have been reported in children.[168,202]

In patients with acute flaccid paralysis, electromyography, and nerve conduction studies document normal nerve conduction velocities, normal or reduced compound muscle action potentials, and normal sensory nerve action potentials consistent with anterior horn cell disease.§ Electrophysiologic documentation of severe loss of sensory fibers exists.[61]

NEUROIMAGING

Magnetic resonance imaging (MRI) is more sensitive than computed tomography in identifying CNS abnormalities in patients with West Nile neuroinvasive disease. However, even in cases of severe encephalopathy, MRI may fail to find any abnormalities.[23] Reported MRI findings in cases of West Nile neuroinvasive disease appear as hyperintense signal on T2-weighted and fluid-attenuated inversion recovery images and are nonenhancing and of normal intensity on T1 weighting.[96,160] In children and adults, lesions tend to be seen more frequently in the deep gray matter of the brain and, in particular, the basal ganglia, posterior thalami, and substantia nigra.* Leptomeningeal and paraventricular enhancement may also be seen.[22,165] Focal abnormalities occasionally may be seen, as noted in two cases of children with encephalitis in whom focal enhancement of the right temporal lobe was noted.[57,66,202]

In cases of acute flaccid paralysis, abnormal T2-weighted signals may be seen in the spinal cord gray matter.[3,86,96,117] In a case of a child with acute flaccid paralysis, magnetic resonance imaging of the spine documented edema of the anterior horns of the cervical spinal cord.[86]

VIRAL CULTURE AND NUCLEIC ACID AMPLIFICATION DETECTION OF WEST NILE VIRUS

Multiple reports have documented that WNV can be detected from the blood and brain of infected individuals by use of mouse inoculation or cell culture.† However, this approach to establishing the diagnosis of WNV infections is of limited utility because of lack of sensitivity resulting from the brevity of the viremia, which begins approximately 2 days before and persists until approximately 4 days after the onset of the illness.[72,158,190] In addition, because of the potential risk to laboratory personnel, attempts to isolate WNV from human specimens should be undertaken only in an appropriate biocontainment environment (i.e., biosafety level 3 containment).

Numerous nucleic amplification assays (i.e., RT-PCR, RT loop-mediated isothermal amplification) for the detection of WNV have been developed.[110,154] Diagnosis of acute WNV infections by nucleic acid amplification–based detection of WNV genome from blood and CSF clinical specimens also has limitations because of the short period of viremia.[110,158] Although genome could be detected in all brain tissue specimens tested, only 57 percent of CSF specimens and 14 percent of sera from patients with serologically confirmed infection were positive by a real-time RT-PCR assay.[110] Nucleic acid amplification–based detection of WNV has not been proved to be useful for the clinical diagnosis of WNV infections, but it has been extremely valuable in the screening and detection of asymptomatic viremia in blood donors.[134]

DETECTION OF WEST NILE VIRUS–SPECIFIC ANTIBODIES

Given the limitations of virologic and nucleic acid amplification–based diagnostic assays, detection of virus-specific antibodies forms the mainstay for establishing the diagnosis of WNV infections. In cases of neuroinvasive disease, the presence of WNV-specific IgM in serum and CSF increases by 10 percent per day the first week of illness such that it is usually detectable in 70 to 80 percent of patients by the eighth day after onset of illness.[85,193] Interestingly, WNV-specific IgM may persist for long periods in serum and CSF of acutely infected individuals.[170] Fifty-eight percent of samples obtained approximately 500 or more days from onset of West Nile encephalitis were in the positive or equivocal range for WNV-specific IgM.[170] Similarly, WNV-specific IgM has been detected in the CSF for up to 199 days after onset of illness.[100]

The interflavivirus cross reactivity of antiflaviviral IgG antibodies is well recognized. Traditionally, confirmation of anti-flaviviral antibody specificity requires the use of a functional antibody assay such as the plaque reduction neutralization test.[120] Although multiple reports have documented greater specificity of antiflaviviral IgM antibodies and, in particular, those of WNV-specific IgM antibodies,[126,127,193] cross reactions may still occur. On the basis of cross reactivity with related flaviviruses (i.e., Japanese encephalitis virus and St. Louis encephalitis virus), an algorithm for the use of CDC-developed IgM capture enzyme-linked immunosorbent assay (MAC-ELISA) has been developed to differentiate human WNV and St. Louis encephalitis virus infections.[127] The algorithm compares the positive-to-negative ratios of WNV-specific and St. Louis encephalitis virus–specific IgM determined in a CDC-standardized MAC-ELISA and has a positive predictive value of 97.8 percent for detection of WNV in the midst of an epidemic. This algorithm has not been validated for commercial MAC-ELISA kits. In the absence of use of the CDC MAC-ELISA, confirmation of WNV infection may require documentation of presence of WNV functional (i.e., neutralizing or hemagglutination inhibition) antibodies.

The diagnosis of WNV infection currently relies on the detection of WNV-specific antibodies in CSF or paired serum samples.[85,175] The MAC-ELISA is the most sensitive and commonly used diagnostic assay. It is capable of detecting IgM antibodies in CSF 3 to 5 days into the clinical illness and 3 or more days earlier than detectable serum antibody.[193] The finding of WNV-specific IgM in the CSF of a child with a clinically compatible CNS syndrome generally is considered diagnostic of acute neuroinvasive infection. However, as discussed previously, persistence of WNV-specific IgM antibodies for as long as 199 days in the CSF has been reported.[100]

Detection of WNV-specific IgM antibodies in serum from a single specimen may not be diagnostic of WNV infection because of its prolonged persistence in serum.[170,175] When only serum is used for establishing a diagnosis, a second serum sample should be obtained at least 2 weeks later to document a fourfold increase in specific antibody titers with use of a functional assay such as neutralization or hemagglutination inhibition.[180] Serologic cross reactions among St. Louis encephalitis virus, WNV, and Powassan virus may occur[195] and can confound the diagnosis in regions where multiple viruses are endemic. Serologic testing ideally should include a battery of region-specific arboviral antigens. Confirmatory assays, such as viral neutralization with the plaque reduction neutralization test, are available from the CDC's Division of Vector-Borne Infectious Diseases, but only 33 percent of commercial diagnostic laboratories and 24 percent of state public health laboratories have the capacity to perform the test.[95] The sensitivities and specificities of commercially available tests for the detection of WNV-specific antibodies may vary. An attenuated immune response may occur in immunocompromised hosts and result in a delayed antibody response.[156] Therefore, serologic assays should be interpreted with caution in this population and adjuncts such as nucleic acid amplification should be used to establish the diagnosis.

NEUROPATHOLOGY

Gross examination of the brain, spinal cord, and meninges generally is unremarkable but may demonstrate evidence of edema. In severe cases, the leptomeninges may show a perivascular monocytic infiltrate on microscopic examination.[196] Although the parenchymal findings of West Nile encephalitis can be seen distributed in nearly all areas of the CNS, the deep nuclei (i.e., thalamus, caudate, and lentiform nuclei), the substantia nigra, and other regions of the brain stem (in particular the pons and medulla), cerebellum, and spinal cord* may be more severely involved.

The CNS pathologic changes are the result of direct viral replication in neuronal and, less so, glial cells as well as the cytotoxic immune response to infected cells.[27,118] WNV demonstrates a penchant for infecting neurons. Viral antigen is detectable in neurons of fatal cases.[8,27,74,191] Neuronal pyknosis or neuronophagia is seen. Features in fatal cases of West Nile encephalitis include perivascular mononuclear inflammatory infiltrates composed predominantly of B lymphocytes, $CD8^+$ T lymphocyte–dominant microglial nodules in the brain parenchyma, and focal mononuclear inflammation along the cranial nerve roots of the medulla.† In the cerebellum, the Purkinje cell layer demonstrates inflammation, neuronal loss, and gliosis.

In cases of acute flaccid paralysis, WNV demonstrates a penchant for infection of the anterior motor neurons. The anterior horns of cervical and lumbar regions are the most severely involved areas.[21,66,74] Evidence of neuronophagia, neuronal loss, and perivascular monocytic infiltrates have been found.[21] Loss of ganglionic neurons, nodules of Nageotte, and perivascular lymphocytic

†References 8, 21, 66, 74, 144, 172.

aggregates have been seen in the dorsal roots and sympathetic ganglia.[21,66]

TREATMENT

Treatment of West Nile fever and neuroinvasive syndromes is primarily supportive. In the case of West Nile encephalitis and meningoencephalitis, close monitoring of respiratory status is essential. Patients with severe muscle weakness, paralysis, dysphagia, or dysarthria may require mechanical ventilation.

No effective antiviral therapy currently is available for the treatment of WNV syndromes. Ribavirin, a broadly active antiviral, has been shown to be active against WNV in vitro and may have as its mechanism of action error-prone replication.[56,98] In the sole pediatric case report, ribavirin was administered orally to a 14-year-old with Hodgkin lymphoma and West Nile meningoencephalitis who recovered completely.[192] Although encouraging, a report of ribavirin in an unblinded, uncontrolled manner for the treatment of WNV infection in 37 patients during an outbreak in Israel in 2000[46] associated its use with a higher mortality rate. Bivariate analysis indicated that its use was associated with a greater likelihood of death (odds ratio, 6.7; 95% confidence interval, 3.0 to 15.2). Because this was an uncontrolled trial, selection bias for its use in more severely ill patients cannot be excluded. However, in a hamster model of WNV infection, ribavirin treatment alone increased the mortality rate.[136] These reports indicate that the use of ribavirin for the treatment of WNV infections appears to be unwarranted and unsupported at this time.

In cell culture, animal models, and a pilot study, IFN-α has been shown to be beneficial against some flaviviruses.[136,164] Although anecdotal reports[99,174] in humans suggest that the use of interferon alfa-2b may improve recovery from West Nile encephalitis, an open label, nonblinded trial did not indicate benefit.[175]

Anecdotal reports of the use of an intravenous immunoglobulin preparation containing a high neutralizing titer of anti-WNV antibodies (Omr-IgG-am) for the treatment of West Nile neuroinvasive disease in adults* and children[22,88] have been published. The limited information suggests a benefit from their use in some but not all cases. A case series suggested that use of hyperimmune gammaglobulin as early as possible in the course of encephalitis may be associated with better outcome.[123]

A humanized monoclonal antibody directed to domain III of the WNV E protein has been developed. It has been demonstrated to be neutralizing and to penetrate the CNS, protecting mice and hamsters against lethal challenge with WNV.[151] In a phase I study it was demonstrated to have mild adverse effects and be well tolerated in healthy adults.[15]

A report of the treatment of macular edema associated with WNV chorioretinitis with bevacizumab has been published.[1] Bevacizumab is a humanized monoclonal antibody that inhibits angiogenesis by inhibition of vascular endothelial growth factor A.

PREVENTION

Prevention of WNV infections requires both community-based public health programs and personal measures. Mosquito abatement through elimination of mosquito breeding sites, use of larvicides to breeding areas, and application of pesticides targeted to adult mosquitoes are approaches used to reduce the abundance of mosquitoes in the environment.

The use and maintenance of door and window screens as physical barriers to prevent mosquitoes gaining access to homes can limit exposure to mosquitoes. Similarly, during engagement in outdoor activities where mosquitoes are prevalent, the use of mosquito netting in sleeping quarters also may decrease exposure to mosquito bites. Individuals should use insect repellent on skin and clothes when exposure to mosquitoes is probable or possible. Repellents such as N,N-diethyl-meta-toluamide (DEET), picaridin, and lemon eucalyptus oil have been shown to be effective and provide long-lasting protection.[10] Soybean oil also has been shown to be effective as a mosquito repellent. Permethrin and DEET have been shown to be effective protection against mosquitoes when applied to clothing.

Finally, avoidance of environments where mosquitoes are found to be in high concentrations and avoidance of outdoor activities during dusk and dawn, when mosquito activity is the highest, should be encouraged. Efforts to prevent transmission of WNV through blood transfusions have led to the use of nucleic acid amplification–based tests for the screening of donated blood. At this time, screening of organ donors for the possible presence of West Nile infection has not been recommended.[102]

The development of WNV vaccines for use in humans has taken various approaches: live attenuated virus, inactivated virus, viral subunits, DNA, vectored virus, pseudoinfectious virions, and chimeric viruses.[13] To date, seven phase I or II vaccine trials have been completed in the United States using a DNA vaccine containing the prM and E coding sequences (NIAID), soluble E protein lacking the C-terminal transmembrane domains, and two chimeric vaccines derived from dengue 4 virus (NIAID) and yellow fever virus (Sanofi-Aventis).[145]

Only the latter has progressed to phase II trials. An infectious clone of yellow fever 17D virus was used as the background for the homologous exchange and insertion of the WNV prM and E genes.[132] The WNV E gene was mutated at three sites to reduce neurovirulence.[7] A phase I chimeric WNV–yellow fever virus vaccine was well tolerated, and the incidences of adverse events were similar in both the vaccine and the placebo groups.[132,184] A transient viremia was observed in 93 percent of recipients of chimeric vaccine. High levels of neutralizing antibodies were detected in 100 percent of the recipients. $CD8^+$ responses were induced in 93 to 100 percent of vaccine recipients. The phase II study[19,12] used a small plaque variant of the vaccine strain, which exhibited reduced viremia in a hamster model. It contained an

additional amino acid mutation in the membrane protein. In part one of the study a short-lived mean viremia was observed but was lower than that seen in the phase I study, regardless of dose of given. Dose ranging studies demonstrated that more than 96 percent of all vaccine recipients developed neutralizing antibodies. The highest dose (3.7×10^5 PFUs) was used for the second part of the study. The mean peak titer of the viremia and its duration was greater in the cohort 65 years of age and older than in the 41- to 64-year-old cohort. Older patients exhibited higher neutralizing titers. Both cohorts had detectable neutralizing antibodies at 12 months and were higher in the 65 years and older cohort.

175C ■ YELLOW FEVER

Duane J. Gubler • Gail J. Harrison

Yellow fever is a mosquito-borne viral disease of humans and lower primates that occurs naturally in tropical Africa and the Americas (Fig. 175C-1). Epidemics, which can occur in both urban and rural areas, often are associated with severe hemorrhagic disease and high fatality rates. It is considered a reemerging disease, with increased incidence documented in the last 25 years.[1] Globally, yellow fever virus infects over 200,000 people every year and causes approximately 30,000 deaths annually.

HISTORY

Yellow fever was described as a disease entity first in 1648 in the Yucatan, Mexico. It apparently was part of a larger regional epidemic that affected the Caribbean islands and Central America from Barbados to Mexico from 1647 to 1649.[14,15] Although it was first described in the Americas, yellow fever virus, along with its principal urban epidemic mosquito vector, *Aedes aegypti*, most likely originated in Africa and was introduced to the New World by the slave trade. During the 17th, 18th, 19th, and early 20th centuries, epidemic yellow fever was a major public health problem in the Western Hemisphere. Large epidemics occurred in tropical America, as well as in the United States (as far north as Boston) and Europe (as far north as England).[24] Epidemics occurred primarily in port cities as a result of spread by sailing vessels and commerce.

After transmission by mosquitoes was documented by Reed and the Yellow Fever Commission in Cuba,[21] major efforts were undertaken to keep the disease in check by mosquito control. The first yellow fever virus was isolated in 1927. By 1938, an effective live attenuated virus vaccine had been developed. Yellow fever was controlled in the Americas by eradication of the mosquito vector of urban disease, *A. aegypti*, from most Central and South American countries. In Francophone countries of West Africa, yellow fever was controlled by mass vaccination programs. The result was the disappearance of major urban epidemics of yellow fever in both Africa and the Americas during the 1950s, 1960s, and 1970s. In the mid-1980s, however, the urban form of disease reemerged in West Africa, with major epidemics in Nigeria and increased transmission in other countries.[14] Kenya experienced its first epidemic in history in 1993. In the Americas, *A. aegypti* has reinfested most Central and South American countries from which it had been eradicated, and urban centers of the American tropics are at their highest risk for epidemic urban yellow fever in more than 60 years.[7] Thus, the disease continues to be an important public health problem in both Africa and the Americas. Yellow fever transmission has never been recognized in Asia or the Pacific.

ETIOLOGIC AGENT

Yellow fever is caused by the yellow fever virus, the prototype of the genus *Flavivirus*, family Flaviviridae. The genus *Flavivirus* contains 53 viruses, which are small (40 to 50 nm in diameter), spherical, and enveloped, with single-stranded RNA approximately 11 kb in length.[5] Many of the flaviviruses are very closely related antigenically, which has resulted in extensive cross reactivity in most serologic tests, so a laboratory diagnosis is difficult

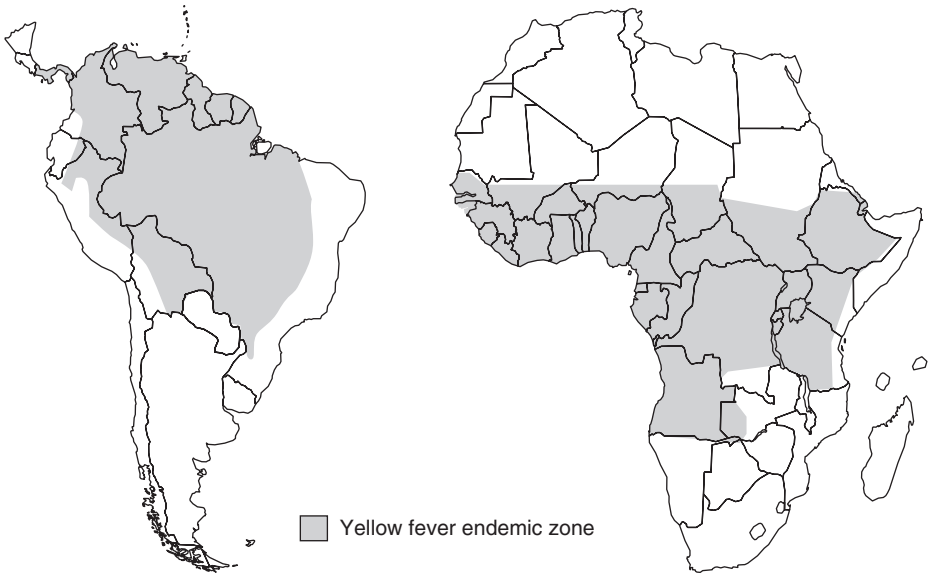

FIGURE 175C-1 ■ Geographic distribution of yellow fever in Africa and the Americas.

to make. Yellow fever virus has seven genotypes that are geographically separated, and outbreaks of disease are more associated with specific genotypes.[1] The virus is part of an antigenic complex that is unique from other members of the family Flaviviridae.[8]

EPIDEMIOLOGY

Yellow fever viruses are maintained in natural zoonotic cycles involving lower primates and canopy-dwelling mosquitoes that breed in tree holes in the rain forests of both Africa and the Americas, called the jungle or sylvatic cycle of yellow fever.[14,16,24] Humans become involved accidentally when they encroach on this forest cycle. Humans thus infected may transport the virus back to a village or city during the incubation period of 2 to 14 days. If infected persons are fed on by urban *A. aegypti*, the virus then can be transmitted to other humans by mosquito bite after an extrinsic incubation of 8 to 10 days. Major urban epidemics are transmitted by this highly domesticated mosquito, which lives in close association with humans in most tropical cities of the world.[1,7]

Yellow fever occurs throughout much of sub-Saharan Africa and tropical America in the sylvatic cycle (see Fig. 175C-1). In Africa, cercopithecoid and celobid monkeys are the main vertebrate hosts; infection rarely causes illness and death in these species. Year-round enzootic transmission by *Aedes africanus* occurs in the rain forests. In wet savanna areas bordering the rain forests of western and central Africa, transmission increases during the rainy season and decreases during the dry season. *Aedes furcifer*, *A. africanus*, and *Aedes leuteocephalus* are the main mosquito vectors in this "zone of emergence," and the virus is transmitted from monkey to monkey, monkey to human, and human to human. In the dry savanna zones, yellow fever activity is intermittent and takes place mainly during the rainy season, but it also occurs in major epidemics in urban areas, where stored water provides the ideal larval habitat for *A. aegypti*. In East Africa, *Aedes simpsoni (Aedes bromeliae)* provides the link between the *A. africanus* sylvatic cycle and humans in areas bordering gallery forests.

In tropical America, howler, spider, squirrel, owl, capuchin, and wooly monkeys all act as vertebrate hosts for yellow fever virus. Mosquitoes of the genus *Haemagogus* are the principal vectors in tropical American rain forests, where they feed in the canopy as well as at ground level. Other mosquito species, such as *Sabethes chloropterus*, *Aedes leucocelaenus*, and *Aedes fulvus*, may play secondary roles. Although most cases of yellow fever have been reported from Bolivia, Brazil, Venezuela, and Peru in recent years, the enzootic zone probably includes the rain forests of at least 10 countries (i.e., Colombia, Ecuador, Peru, Bolivia, Brazil, Venezuela, Guyana, Suriname, French Guiana, and Trinidad[27]) and involves "wandering" enzootic transmission among the monkey populations. The humans involved are mainly adult men who work in the forest.

Vertical transmission of yellow fever virus from an infected female mosquito through the eggs to her offspring plays an important role in survival and maintenance of yellow fever virus in enzootic cycles and has been demonstrated in nature in West Africa by isolation of the virus from male *A. furcifer* mosquitoes. Experimentally, *Haemagogus* and *A. aegypti* mosquitoes have been shown to be capable of vertical transmission. This mechanism is thought to be of major importance in survival of the virus during prolonged dry periods in both enzootic regions.

Urban epidemics of yellow fever have reappeared in West Africa in the past 17 years.[20] Unfortunately, surveillance is very poor, and the actual number of cases reported is thought to be grossly underestimated. For example, in Nigeria in 1986 and 1987, the number of reported cases and deaths during epidemics was 2612 and 973, respectively. Seroepidemiologic studies, however, estimated that the actual number of cases and deaths was 130,000 and 29,000, respectively.[20]

In the Americas, the last urban yellow fever epidemic occurred in 1942. Reinvasion of American tropical urban centers by *A. aegypti*, however, has placed more than 300 million susceptible individuals at risk. As might be expected, urban transmission has been reported recently. In 1998, urban transmission of yellow fever was documented in Santa Cruz, Bolivia.[26] Although not comprising a large number of cases, this outbreak underscores the high risk that many tropical urban centers have at the beginning of the 21st century. In addition, six fatal cases of yellow fever in travelers who visited South America (four cases) or Africa (two cases) in recent years have been confirmed. Three of these cases were U.S. citizens, and three were European. Why contemporary yellow fever epidemics have not occurred in the Americas, despite the high risk, is not known. The dramatic increase in transmission of dengue in urban centers of the American tropics in recent years possibly has resulted in a high prevalence of heterotypic flavivirus antibody that protects against severe yellow fever clinical illness. Another possibility is that the enzootic virus strains are not well adapted to urban transmission by *A. aegypti*.

Epidemic yellow fever has never been reported in Asia or the Pacific. The reason is not known, but both variation in mosquito vector competence and partial protection by heterotypic flavivirus antibody have been suggested as reasons that this virus has never become established in that part of the world. If urban epidemics do occur in the American tropics, however, the virus is expected to move very quickly to this and other permissive areas where urban *A. aegypti* mosquitoes are found; this movement undoubtedly would cause a major international public health emergency.

CLINICAL MANIFESTATIONS

Infection with yellow fever virus causes a spectrum of illness ranging from inapparent infection to severe yellow fever with the classic triad of jaundice, hemorrhage, and albuminuria, which is associated with a high case-fatality rate. Most yellow fever infections are manifested clinically as a mild to severe viral syndrome without

symptoms of intoxication; 10 to 20 percent of infections may result in classic yellow fever.[13,16,17]

The incubation period may be as long as 13 days but generally is 3 to 6 days.[16] The onset of illness is abrupt, with fever, headache, backache, myalgia, nausea, and other nonspecific signs and symptoms. In mild cases, the illness will last for several days, after which recovery is uneventful and complete. In severe cases, prostration occurs commonly, and examination reveals congestion of the skin, conjunctivae, and mucous membranes. The pulse rate usually increases early in the illness, and blood pressure is normal. Leukopenia is a frequent finding, and mild albuminuria may be noted. The temperature generally ranges between 38.5° and 40°C (101.3° and 104°F). Nausea and vomiting are common manifestations. Minor hemorrhagic manifestations such as epistaxis and bleeding gums may be observed. This period of infection may last for approximately 3 days, at which time the congestion declines and a relative bradycardia may occur despite the elevated temperature (Faget sign). The temperature falls to or below normal, and the patient feels better.

In most patients, this period of remission signals the beginning of convalescence; but in severe cases, it may last only a few hours, after which the patient enters a period of intoxication characterized by venous congestion and extreme bradycardia, despite a secondary rise in temperature. Nausea and vomiting are severe and associated with epigastric pain. Prostration, jaundice, marked albuminuria, and anuria are present. Hemorrhagic manifestations include hematemesis and melena.

The jaundice in some patients is not striking; it is difficult to detect in early disease and often is not detected until after death. The severity of hemorrhagic manifestations also varies greatly, but some hemorrhage can be found in most cases. As indicated earlier, minor hemorrhagic manifestations may be observed in the early stage of illness; severe hemorrhage usually develops late in the illness, although it may occur in fulminant cases as early as the second or third day. Hemorrhage may be so severe that it causes shock and death from blood loss. Albuminuria is one of the most common findings in yellow fever, and it occurs in all but very mild cases. It is present early in the illness and may increase rapidly. The albuminuria probably is related to renal involvement during the period of infection. Anuria, on the other hand, appears to be related to hepatic involvement and never is seen in the absence of other signs of liver infection. These terminal events may be related to "cytokine storm."

Death may ensue as early as 2 to 4 days after onset but usually occurs after 7 to 10 days of illness in 20 to 50 percent of severe cases. In patients in whom death occurs later, autopsy generally reveals a cause other than yellow fever. Patients with severe infection often have lowered resistance to secondary infection, which may develop at the time of convalescence. Other complications include kidney abscess, pneumonia, suppurative parotitis, and skin infection. Convalescence usually is rapid and complete except for a general weakness that may last for several weeks. Permanent damage to the liver or kidneys is not apparent.

PATHOLOGY

The gross pathologic findings in fatal cases of yellow fever is not striking.[17] The skin, sclerae, serosa, some internal organs, and subcutaneous fat usually have moderate icterus. Serous effusions, edema, and hemorrhages, including petechiae and purpuric lesions on the skin, conjunctivae, mucous membranes, stomach, duodenum, and bladder, often are present. Gastrointestinal hemorrhage may be prominent.

The most characteristic lesions caused by yellow fever virus are seen in the liver, although liver failure is not generally the cause of death. The liver may have a yellowish color and be enlarged and fatty in consistency. In typical cases, marked necrosis of the midzone of the lobule is present. The necrosis extends both centrally and peripherally and on average involves 80 percent of the lobule in fatal cases.[13,17] The cells bordering the central vein and portal areas usually are spared. Councilman and Torres bodies can be observed in hepatocytes. Little or no inflammatory response occurs, and the reticulin framework is preserved.

The kidneys generally are tense and swollen. Glomerular changes are minor, but acute tubular necrosis and fatty metamorphosis may be significant. Cloudy swelling, degeneration, and fatty infiltration may occur in the myocardial fibers. The spleen and lymph nodes are depleted of lymphocytes, and mononucleocytes or histiocytes accumulate in the follicles of the spleen. Edema and petechiae may be observed in the brain.

LABORATORY FINDINGS

Leukopenia and albuminuria are common findings in early stages of the disease. In severe cases, prolonged prothrombin and partial thromboplastin times, thrombocytopenia, fibrin split products, and elevated liver enzymes are observed. Total and conjugated serum bilirubin levels are elevated. Albumin levels in urine usually are less than 5 g/L, but in rare cases they may reach 40 g/L. The urine contains bile. Cerebrospinal fluid usually is normal but may be under increased pressure.

DIFFERENTIAL DIAGNOSIS

Clinically, yellow fever is difficult to differentiate from many other viral, bacterial, and parasitic infections, including other viral hemorrhagic fevers such as Lassa, Ebola, Marburg, and Rift Valley in Africa; the illnesses caused by arenaviruses in the Americas; and dengue hemorrhagic fever in both continents. Other diseases that cause fever and jaundice, such as viral hepatitis, leptospirosis, falciparum malaria, tick-borne relapsing fever, typhus, typhoid, and Q fever, also should be considered in the differential diagnosis. A definitive diagnosis of yellow fever can be made only by use of the appropriate laboratory test.

LABORATORY DIAGNOSIS

Specific laboratory diagnosis requires isolation of the virus or serologic, nucleic acid amplification, or immunohistochemical tests. Virus can be isolated most easily from acute-phase serum taken during the first 4 days of illness, but it has been isolated as long as 14 days after the onset of illness and from the liver after death.[17] The most sensitive method of virus isolation is inoculation of mosquitoes followed by AP-61 cell culture from *Aedes pseudoscutellaris* mosquitoes. Vero cells and inoculation of suckling mice also can be used but are less sensitive. Polymerase chain (PCR) reaction is highly sensitive, and yellow fever RNA can be amplified from these same tissues with a sensitivity higher than that of virus isolation.[7,11] Viral antigen can be demonstrated in the liver by immunohistochemical methods.[9] Either fresh or formalin-fixed tissue can be used with these techniques, which may be performed to establish a virologic diagnosis after virus has been cleared from the blood.

Serologic diagnosis depends on the collection of properly timed acute- and convalescent-phase serum samples to demonstrate a rise in specific antibody. Serologic tests commonly used to diagnose yellow fever include hemagglutination inhibition, complement fixation, and the plaque reduction neutralization test (PRNT) as well as newer tests, such as enzyme-linked immunosorbent assay (ELISA) for both immunoglobulin (Ig)G and IgM antibodies.[8] The immunofluorescent assay is used in some laboratories.

Antibodies detected by hemagglutination inhibition, PRNT, immunofluorescent assay, and IgM capture ELISA appear within 5 to 7 days after the onset of illness, whereas complement-fixation antibodies appear later, usually after 10 to 14 days. Hemagglutination-inhibition and PRNT antibodies persist at detectable levels for many years (>50) in most patients, whereas the duration of complement-fixation and IgM antibodies is uncertain, but they probably wane to undetectable levels after 12 to 18 months.

PRNT is the most sensitive and specific of the serologic tests.[23] In patients who have had no previous flavivirus infection, this test can be used to make a specific diagnosis of yellow fever, as can IgM capture ELISA. Cross reaction between yellow fever antigen and antibodies to other related flaviviruses complicates the serodiagnosis of this and other flavivirus diseases. Hemagglutination inhibition, immunofluorescent assay, and IgG ELISA are nonspecific tests in which considerable cross reactivity with heterologous flavivirus antibodies occurs.

The use of yellow fever 17D vaccine in disease-endemic areas also may complicate serologic diagnosis. Vaccination induces low-titer (1:10 to 1:40) hemagglutination-inhibition and neutralizing antibodies but no detectable immunofluorescent or complement-fixation antibodies. Vaccination also induces IgM antibody, which may remain at detectable levels for as long as 3 to 4 years.[6,22] Vaccination of individuals who have had a previous flavivirus infection induces an anamnestic response of heterotypic flavivirus antibodies at high titer (≥1:1280).[12]

Yellow fever virus genome also may be detected by molecular methods such as quantitative real-time PCR and isothermal protocols that have been simplified and used in reference laboratories and point-of-care field situations.[4,11]

TREATMENT

Treatment of yellow fever is primarily supportive. No specific antiviral therapy is licensed for treatment of yellow fever.[13,15] However, ribavirin has activity against yellow fever virus and has been used to treat other *Flavivirus* infections.[18] In addition, investigations on the use of compounds such as T-705 and T-1106, as well as derivatives of the antibiotics doxorubicin and teicoplanin, as inhibitors of yellow fever virus replication are reported.[3,10] Patients with severe disease requiring hospitalization should have complete bed rest with good nursing care and close monitoring of vital organ functions. Salicylates should be avoided, but mild sedatives may be helpful. Maintenance of fluid and electrolyte balance is critical. Guidelines for intensive care of severe yellow fever cases have not been established. Secondary bacterial infections may occur and should be treated with appropriate antibiotics.

PROGNOSIS

Mortality in all yellow fever infections is low (<5%), but in severe cases requiring hospitalization, it may be 20 to 50 percent.[13,17] The prognosis is poor for patients who enter a period of intoxication with rapidly increasing albuminuria, jaundice, fever, and severe hemorrhage. Patients in the terminal stage of illness usually are somnolent, have below-normal temperatures, and may have intractable hiccups.

PREVENTION AND CONTROL

The most practical and cost-effective method of preventing yellow fever is vaccination. A single dose of 17D vaccine provides effective, long-term (10 years) protection and should be used in the World Health Organization Expanded Program of Immunization in enzootic countries of Africa and the Americas.

The live attenuated 17D vaccine is prepared from infected chicken embryos and produces effective immunity in more than 95 percent of recipients.[2,17] It is used to provide protection for travelers to and residents of endemic areas of tropical South America, South Africa, and Africa. The decision to administer yellow fever vaccine should include the geographic destination, season of the year, local evidence for yellow fever transmission, likelihood of exposure to vector mosquitoes, and individual risk factors for adverse events.[2,17,19] Adverse reactions rarely occur, but may be categorized as neurotropic or viscerotropic. Adverse events may occur more often in elderly persons, infants, and pregnant women.[2,12,17,19] The elderly appear to have a delayed antibody response and a

prolonged viremia after vaccination, possibly leading to the higher incidence of adverse events in the older age group.[12,22] Infants younger than 4 months of age have a high risk for development of encephalitis and should not be vaccinated with the live attenuated 17D vaccine until they are 9 months of age. Pregnant women also should avoid being vaccinated because vaccine virus may infect the developing fetus, although the risk for adverse events associated with congenital infection is unknown. The live attenuated 17D vaccine should not be given to persons who are allergic to eggs or to those who are immunodeficient or receiving immunosuppressive drugs. Detection of yellow fever IgG antibody persists, and detection of yellow fever IgM antibodies may persist up to 3 to 4 years after vaccination, confounding serologic diagnosis of yellow fever in vaccinated travelers.[6]

The other method of preventing yellow fever is mosquito control, especially during epidemic activity. The principal mosquito vector of urban yellow fever, *A. aegypti*, is a highly domesticated species that lives in and around the houses of humans.[1,7] It breeds primarily in artificial containers that collect rainwater or in domestic water storage containers, and is notoriously difficult to control. The most sustainable and effective prevention, therefore, is to control, discard, or chemically treat larval habitats in the domestic environment.[1,7] This process is labor-intensive but can be done with the help of the citizens in the community.

Some authorities recommend adult mosquito control with insecticide space sprays, primarily ultra-low-volume sprays. Recent field trials, however, have shown this approach to be ineffective unless portable sprayers are used to treat the inside of each dwelling. Because of the excessive cost and lack of efficacy of ultra-low-volume application of insecticides, this method is not recommended.

Recently, the ability of the intracellular bacterium *Wolbachia* to reduce the replication of yellow fever virus in the mosquito vector *Aedes aegypti* shows promise for a novel biocontrol strategy for yellow fever.[25]

Patients suspected of having yellow fever should be protected from mosquitoes. The most effective protection is to use a mosquito net on the bed during the acute febrile period of illness. Alternatively, patients can be kept in screened rooms. Effective repellents are available to treat clothing and exposed skin.

175D ■ DENGUE, DENGUE HEMORRHAGIC FEVER, AND SEVERE DENGUE

Scott B. Halstead

Dengue fever is an acute febrile illness syndrome caused by several arthropod-borne viruses and characterized by biphasic fever, myalgia or arthralgia, rash, leukopenia, and lymphadenopathy. Synonyms are dengue and breakbone fever. Dengue hemorrhagic fever (DHF), a febrile disease syndrome caused by dengue viruses, is characterized by abnormalities in hemostasis and leakage of fluid and protein from capillaries, which in severe cases results in shock (dengue shock syndrome [DSS]). It is thought to have an immunopathologic basis. Synonyms are hemorrhagic dengue; acute infectious thrombocytopenic purpura; and Philippine, Thai, Singapore hemorrhagic fever and recently introduced World Health Organization (WHO) case definitions, dengue with warning signs and severe dengue. Useful general reviews are available.[66,150]

The dengue subgroup is composed of four antigenically distinct members.[36,74,88,142] In the second decade of the 21st century, dengue viruses were epidemic and endemic in 110 tropical countries according to reports received by the WHO and other sources, with nearly 3 billion people at risk for infection, an estimated annual 10 million cases of dengue fever, 250,000 children and adults hospitalized, and case fatalities in some countries of 5 percent.[13,58] In tropical Asian countries, dengue is among the 10 leading causes of death in children ranging in age from 1 to 15 years.[64] Small indigenous outbreaks of dengue 1 occurred in Hawaii in 2001 and Key West,

Florida in 2009 to 2011.[41,125] Dengue infections are major causes of febrile illnesses in tourists to tropical destinations, some of whom develop life-threatening disease.[175,176]

The term *dengue*, of Spanish origin, came into use in 1828 during a Cuban outbreak that undoubtedly was chikungunya.[22] The Swahili term for chikungunya, *ki denga pepo*, had been used to describe an 1823 outbreak on Zanzibar.[29] The first outbreak that resembled a disease now recognized as dengue fever was described by Benjamin Rush in Philadelphia, Pennsylvania, in 1780.[22,148] Epidemics probably caused by dengue viruses were common from the 18th to the 20th centuries in inhabitants of the Atlantic coastal areas of the United States and South America, the Caribbean islands, and the Mississippi basin.[148] Dengue viruses almost certainly were the cause of the 5- and 7-day fevers that occurred in European colonists in tropical Asia. Similar epidemics occurred commonly in settlers in tropical Australia, where in 1905 *Aedes aegypti* was identified as a dengue vector by Bancroft.[10] Ashburn and Craig[7] found the etiologic agent in human blood and showed that it could pass through a diatomaceous earth filter. An intrinsic incubation period of 3 to 8 days in humans, an extrinsic incubation period of 8 to 11 days in mosquitoes, immunity in humans and monkeys, and the nonsusceptibility of most domestic animals were demonstrated in the classic studies of Siler and associates[148] and Simmons and coworkers[151] between 1924 and 1930. When dengue viruses were isolated in laboratory mice in 1943 and 1944, the modern era of dengue research began.[91,144] Two strains from Hawaii and Papua New Guinea failed to cross protect humans. From this experiment, researchers recognized the existence of at least two different dengue viruses; they were named dengue viruses type 1 and type 2.[143,144]

During most of the previrologic era, dengue viruses were thought to be the cause of a generally benign, self-limited febrile exanthem. However, death, shock, and severe hemorrhagic manifestations accompanied classic dengue fever outbreaks in Australia in 1897 and thereafter for 15 years. Similar phenomena were recorded in Greece in 1928 and in Formosa in 1931.[55] This "new" syndrome was recognized again in Manila in 1954. It was called Philippine hemorrhagic fever because of a resemblance to the epidemic hemorrhagic fever then occurring in United Nations troops in the Korean Peninsula.[74] In 1956, Philippine hemorrhagic fever was associated with dengue when types 3 and 4 were recovered.[74] All four dengue viruses are now endemic in tropical countries throughout the globe.[64,65] Since 1966, the terms *dengue hemorrhagic fever* and *dengue shock syndrome* (DSS) came into general use.[33,55] In 2009, a WHO committee advised that these terms be subsumed under the diagnostic categories, "dengue with warning signs" and "severe dengue."[184]

By epidemiologic criteria, dengue viruses are arthropod-borne (arboviruses) because they are transmitted biologically by various members of the genus *Stegomyia*.[111] Gene structure, replicative strategy, and antigenic relatedness place the dengue viruses in the family Flaviviridae.[88,170] At present, 68 members of the flavivirus family have been identified; 29 of them are established as human pathogens.[88] Cross comparisons by plaque reduction neutralization tests have shown dengue viruses to be an antigenic subgroup.[35] In addition to their antigenic relatedness and their ability to be transmitted by *Stegomyia*, each type of dengue virus produces a closely similar clinical syndrome in susceptible humans.[57,143,148,151]

Dengue virions are spherical particles approximately 50 nm in diameter. The central core, approximately 25 nm in diameter, has icosahedral symmetry and contains a single plus strand of RNA. Dengue RNA consists of approximately 11,000 nucleotides coding from the 5′ end for core, premembrane, envelope, and five nonstructural proteins.[54] Large amounts of nonstructural protein 1 (NS1) are released from infected cells.[104,188] The envelope, which is studded with poorly resolved projections, is composed of many replicates of the envelope protein (54 kDa) embedded in a lipid bilayer. When it is assembled on the virion, the envelope protein bears some epitopes unique to serotypes. Antibodies to these epitopes neutralize by hindering viral attachment or entry into cells.[123] Other epitopes are shared between dengue viruses (dengue subgroup antigens) and other flaviviruses (group antigens).

Four clearly defined types exist, as determined by plaque reduction neutralization tests using antibodies raised by infection of monkeys or fluorescent antibody tests using monoclonal antibodies raised in mice.[34,141] Presumably, virion structures differ for each dengue serotype with the result that infection is blocked by homotypic neutralizing antibody.[35,76] The four types have distinctive genetic structures.[174] Phylogenetic studies suggest that human dengue viruses diverged from four zoonotic dengue types relatively recently, whereas the four zoonotic types evolved from a common ancestor in the more remote past.[78,163,170] Sylvatic dengue viruses retain the capacity to infect and cause disease in humans.[21,164] Different dengue strains cluster in groups that differ genetically (genotypes).[30,31,129,130,160] Genotypes consist of viruses of similar genetic structure that usually circulate within one geographic area.[160] Genotyping can be used to trace the movement of dengue viruses between persons over short and long distances.[84] Of particular interest, a strain of dengue type 2 isolated in Jamaica in 1981 and the dengue 2 viruses recovered from 1981 Cuban DHF patients belong to a Southeast Asian genotype.[129,145] The most sharply divergent genetic differences are among human viruses and strains from Asian and African zoonotic cycles.[129,163,170]

Dengue virus can be grown in 1- to 2-day-old mice or hamsters by intracerebral inoculation or in various mosquitoes by oral or parenteral inoculation. High mouse-passaged virus grows and produces deaths in weanling mice. Various tissue cultures of vertebrate and invertebrate origin support dengue virus growth in vitro, as reviewed in the following section.

TRANSMISSION

A. aegypti, a crepuscular daytime-biting mosquito, is the principal vector. All four virus types have been recovered from naturally infected *A. aegypti*.[55] In most tropical

areas, *A. aegypti* is highly domesticated and breeds in water stored for drinking, washing, or bathing or in any container collecting fresh water. Dengue viruses also have been recovered from naturally infected *Aedes albopictus*, which breeds outdoors in vegetation.[41,55] Outbreaks in the Pacific area have been attributed to *Aedes scutellaris* and *Aedes polynesiensis*.

Transmission of dengue by *A. aegypti* may be explosive and involve as much as 70 to 80 percent of the population.[148] Because *A. aegypti* has a limited flight range, spread of virus is mainly by mobile viremic humans.[105,187] Transmission of dengue viruses by *A. albopictus* results in indolent, long-duration small outbreaks, as exemplified by the introduction of dengue virus type 1 into Hawaii in 2001.[41]

Dengue viruses replicate in the gut, brain, and salivary glands of infected mosquitoes without apparent harm to adult mosquitoes.[135] Mosquitoes are infectious for a lifetime and as long as 70 days in experimental circumstances.[151] Because female mosquitoes take repeated blood meals, long-lived female mosquitoes have great potency as vectors. Several species of *Stegomyia* are infected readily by intrathoracic inoculation, although the threshold for infection by oral feeding is higher.[134,135] *A. aegypti* and *Culex quinquefasciatus* can transmit dengue mechanically by interrupted feeding.[62,151] The contribution of mechanical feeding to the spread of dengue virus during epidemics has never been measured. Because of the "skittishness" of *A. aegypti* and its habit of feeding during the day when its intended victim is awake and often moving, interrupted feeding with simultaneous transmission to multiple hosts within a household must be a common occurrence.

A. aegypti preferentially feeds on people and hence is most abundant in and around human habitations. The mosquito breeds in clean water. Biting activity is reduced at temperatures below a wet bulb temperature of 14° C (57.2° F).[36] Transmission of dengue in temperate countries is interrupted during winter weather, and dengue has not established itself endemically at latitudes above 25 degrees north or south. Breeding sites may be provided by humans through living habits, as in Thailand, where water is stored in and around homes in large earthenware jars.[55,62] In contrast, *A. aegypti* is not abundant in some parts of India because only small amounts of water are brought to homes from village wells for immediate use. Water in flower vases, household offerings, ant traps, coconut husks, tin cans, and rubber tires may supply breeding sites for *A. aegypti*.[47]

In the tropics, outbreaks of dengue generally coincide with the monsoon season. Eggs, which resist desiccation, are deposited inside water containers above the water line.[47] With the beginning of monsoon rains, a large number of eggs laid outdoors are hatched.[68] Indoor populations do not show seasonal change. Temperature is important in controlling viral transmission. Evidence indicates that the extrinsic incubation period shortens with increasing mean temperatures; mosquito biting rates increase with increased temperature and relative humidity.[147]

In sylvan settings, dengue virus has been isolated from three subgenera of *Aedes*, namely, *Stegomyia*, *Diceromyia*, and *Finlaya*, some in circumstances suggesting the occurrence of transovarial transmission. This phenomenon has been demonstrated experimentally, but its contribution to maintenance of virus in a habitat is unknown.[137]

EPIDEMIOLOGY

Host Range

Inoculation of strains of dengue with known human pathogenicity does not produce demonstrable infection in adult chickens, lizards, guinea pigs, rabbits, hamsters, or cotton rats.[146,151] Subhuman primates generally are susceptible to infection by dengue viruses. Numerous species belonging to *Macaca*, *Cercopithecus*, *Cercocebus*, *Papio*, *Hylobates*, and *Pan* can be infected by the bite of virus-infected mosquitoes or by injection of infectious virus preparations.[60,146,151] Infection is essentially asymptomatic. Viremia occurs at levels sufficient to infect mosquitoes. Simmons and colleagues were the first to note that wild-caught *Macaca philippinensis* resisted dengue infection, whereas *Macaca fuscatus* (Japanese macaque) was susceptible.[151] Work by Rudnick[140] in Malaysia has revealed a jungle cycle of dengue transmission involving canopy-feeding monkeys and *Aedes niveus*, a species that feeds on both monkeys and humans. Although the existence of a jungle dengue cycle in the Malaysian rain forest has been documented, the full geographic range of the subhuman primate zoonotic reservoir is not known. In the 1980s and 1990s, extensive epizootics of dengue virus type 2 involved subhuman primates over wide areas of West Africa.[132,166] Genetic and epidemiologic studies have shown that urban human dengue and jungle monkey dengue are only relatively compartmentalized.[129,165,170] Urban dengue is vectored by anthropophilic mosquitoes, and the virus travels along routes of transportation.[105] *A. aegypti* and susceptible humans are so abundant and so widespread that should dengue viruses be exchanged between humans and monkeys, detection would be extremely difficult. If, in the future, urban dengue is eliminated but vector mosquito populations are unabated, dengue viruses may once again be introduced from jungle cycles.

GEOGRAPHIC DISTRIBUTION

Outbreaks of dengue fever have been documented on every continent except Antarctica.[55] Evidence suggests that human dengue may have originated from enzootic foci in tropical Asia.[170,172] The probable spread of *A. aegypti* during historical times from Africa throughout the world provided an ecologic niche quickly occupied by several human viral pathogens: yellow fever, chikungunya, and the dengue viruses. During the 18th and 19th centuries, epidemics occurred in newly settled lands, largely because of the necessity for storage of domestic water in frontier areas. Isolated shipboard or garrison outbreaks often confined to nonindigenous settlers or visitors were reported in Africa, the Indian subcontinent, and Southeast Asia.[24,107,148] During World War II, dengue

virus infections occurred commonly in combatants of the Pacific War and spread to staging areas not normally infected—Japan, Hawaii, and Polynesia.[64,67,143] DHF-like disease was described clinically in Thailand beginning in 1950 and in the Philippines from 1953; cases were confirmed etiologically as dengue in 1958 and 1956, respectively.[74] DHF first was described in Singapore and Malaysia in 1962, Vietnam in 1963, India in 1963, Ceylon (Sri Lanka) in 1965, Indonesia in 1969, Burma (Myanmar) in 1970, China in 1985, and Kampuchea and Laos from about 1985; major outbreaks have occurred in Sri Lanka and India since 1988, in French Polynesia since 1990, in Pakistan since 1998, and in Bangladesh since 1999.[59,64,67] DHF has occurred at consistently high endemicity in Thailand, Burma, Vietnam, Cambodia, Laos, Philippines, India, and Indonesia.[67] Since 2008, repeated outbreaks have occurred in Pakistan.[81] In Thailand, DHF is the third ranking cause of hospitalization and death in children. Intermittent epidemics have involved the Maldives, Singapore, and Bangladesh.

During the past 20 years, major epidemics of all four dengue serotypes have occurred on several Pacific islands, with repeated severe epidemics on Tahiti.[31,48,64,79]

American genotype dengue 2 virus circulated in the American hemisphere for hundreds of years and was the only virus to survive an intensive period of control of *A. aegypti* designed to eradicate urban yellow fever.[5] In 1963, an Asian strain dengue 3 was introduced into the Caribbean and died out in the 1980s. Dengue viruses became fully established in the hemisphere after the introduction of a Southeast Asian dengue 1 in 1977.[65,121] Dengue 1 spread rapidly and now is endemic on the larger Caribbean islands and in Mexico, coastal Central America, and the tropical areas of Guyana, Venezuela, Colombia, Ecuador, Peru, Bolivia, and Brazil.[65] A sharp dengue virus type 2 epidemic in Cuba in 1981 involving 116,000 hospitalizations in a 3-month period led to apparent eradication of *A. aegypti*, but reintroduction of dengue type 2 into Santiago de Cuba in 1997 and type 3 in Havana in 2001 resulted in particularly severe outbreaks of DHF.[2,53,95] In 1981, an Asian dengue 4 was introduced into the Caribbean, spread widely, and now is endemic throughout the Caribbean basin. In 1986 and 1987, dengue virus type 1 spread through most of coastal Brazil and from there to Paraguay, Peru, and Ecuador.[126] In 1990, more than 9000 dengue cases were reported from Venezuela; 2600 of them were classified as DHF, and 74 deaths were associated with the epidemic.[126] Dengue virus types 1, 2, and 4 were isolated.[126] Shortly thereafter, DHF/DSS caused by dengue type 2 was reported from Brazil and French Guiana.[118,127] In 1994, dengue virus 3 was introduced into the region.[65] Dengue virus types 1 to 3 are now endemic in most of Brazil. Initially, in the Americas most dengue infections produced disease in adults, occasionally severe but of low mortality. As two or more dengue viruses became endemically established, classic DHF was recognized throughout most of South and Central America with severe disease increasingly involving children.[65,133]

In the 1960s, dengue viruses 1 and 2 were recovered from humans with mild clinical illnesses in Nigeria in the absence of epidemic disease.[23] In 1983, dengue virus type 3 was isolated in Mozambique.[64] Since then, all four dengue virus types have been recovered from individuals with febrile diseases in much of Africa or travelers returning from Africa.[3] Dengue virus type 3 infections were notable in the past decade with a sharp outbreak of classic dengue fever observed in adults on the Cape Verde islands, and cases and deaths resulting from classic DHF/DSS in Kassala, Sudan, and Port Sudan on the Gulf of Aden.[1,6,108] In Sub-Saharan Africa, DHF/DSS have not been reported and even dengue fever outbreaks are rare. In this respect, Sub-Saharan Africa resembles the situation in Haiti, where multiple dengue serotypes are transmitted at high rates among a predominantly black population but severe disease is not recognized.[73,131]

CLINICAL MANIFESTATIONS

Dengue Fever

In classic dengue fever (seen most frequently in adults), after an incubation period of 2 to 7 days, patients experience a sudden onset of fever, which rapidly rises to 39.5° to 41.4°C (103°F to 106°F) and usually is accompanied by frontal or retro-orbital headache. On occasion, back pain precedes the fever. A transient, macular, generalized rash that blanches under pressure may be seen during the first 24 to 48 hours of fever. The pulse rate may be slow in proportion to the degree of fever. Myalgia or bone pain occurs soon after onset and increases in severity. During the second to sixth day of fever, nausea and vomiting are likely to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgesia, aberrations in taste, and pronounced anorexia may develop.

One or 2 days after defervescence, a generalized morbilliform, maculopapular rash appears, with sparing of the palms and soles. It disappears in 1 to 5 days. In some cases, edema of the palms and soles may be noted, and desquamation may occur. About the time of appearance of this second rash, the body temperature, which has fallen to normal, may become elevated slightly and establish the biphasic temperature curve.

Epistaxis, petechiae, and purpuric lesions are uncommon manifestations but may occur at any stage of the disease. Swallowed blood from epistaxis may be passed per rectum or be vomited and could be interpreted as bleeding of gastrointestinal origin. In adults, gastrointestinal bleeding, menorrhagia, and bleeding from other organs have been observed in some dengue fever outbreaks.[128,161,173] Very clear evidence argues that dengue infections in individuals with peptic ulcer predisposes to gastrointestinal hemorrhage; in some cases, patients may exsanguinate during an otherwise normal dengue fever.[161] This syndrome may be confused with DSS (see later discussion) and contribute to a misunderstanding of its pathogenesis. The mechanism of the hemorrhagic diathesis that commonly occurs with dengue virus infection is not known, but speculation centers on platelet abnormalities. The DHF syndrome is differentiated from dengue fever by its association with hemostatic abnormalities and capillary leakage.[155] After the febrile stage,

prolonged asthenia, mental depression, bradycardia, and ventricular extrasystoles are noted commonly in adults.[107]

Primary infections with dengue virus types 2 and 4 are thought to be largely inapparent, particularly in children.[53,87,167,168] Primary infections with dengue virus types 1 and 3 in children often result in mild to moderate febrile disease, sometimes accompanied by low-grade vascular permeability. Infections with these two viruses in adults produce biphasic fever and rash as the most characteristic features of the dengue fever syndrome.[42,151] Manifestations vary with age and among patients. In infants and young children, the disease may be undifferentiated or characterized by a 1- to 5-day fever, pharyngeal inflammation, rhinitis, and mild cough.[71] A distinctive mean incubation period, duration of illness, or spectrum of clinical findings could characterize disease with different dengue types, although these factors have not been studied carefully. As dengue infections spread around the world, persons of all ages are experiencing their first or successive dengue infection as adults. In some cases, dengue infections, whether primary or secondary, in adults or the elderly, particularly those with diabetes, asthma, or hypertension, are serious and pose a risk for death.[98-100,103,122]

Differences in mild dengue syndromes, hospitalized dengue cases (predominantly during secondary dengue virus infections), and chikungunya illnesses are illustrated in the section on chikungunya. Chikungunya virus infections produce a dengue fever syndrome. Because chikungunya and the dengue viruses are transmitted by the same vector mosquitoes, the diseases frequently are observed in the same patient populations. Chikungunya illnesses begin more abruptly than dengue illnesses and are of shorter duration. Maculopapular rash, conjunctival injection, and myalgia or arthralgia occur more frequently in chikungunya than in dengue illnesses, but other features associated with both viruses are remarkably similar.[22,116]

Dengue Hemorrhagic Fever/Dengue Shock Syndrome

DHF/DSS is an acute vascular permeability syndrome accompanied by abnormal hemostasis. The incubation period of DHF/DSS is unknown but is presumed to be the same as that of dengue fever. In children, progression of the illness is characteristic.[33,115,116,177] A relatively mild first phase with an abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough may be followed after 2 to 5 days by rapid deterioration and physical collapse. In Thailand, the median day of admission to the hospital after the onset of fever is day 4. In this second phase, the patient usually has cold and clammy extremities, a warm trunk, a flushed face, and diaphoresis. Patients are restless and irritable and complain of midepigastric pain. Frequently, scattered petechiae appear on the forehead and extremities, spontaneous ecchymoses may develop, and easy bruisability and bleeding at sites of venipuncture are common findings. Circumoral and peripheral cyanosis may occur. Respirations are rapid and often labored. The pulse is weak, rapid, and thready, and the heart sounds are faint. Systolic pressure may remain normal or even elevated, and the patient appears deceptively well, retaining full consciousness. Once hypotension ensues, the pulse pressure becomes narrow (<20 mm Hg) and systolic and diastolic pressure fall rapidly and may become unobtainable. The liver may become palpable two or three fingerbreadths below the costal margin and usually is firm and nontender. Chest radiographs show unilateral (right) or bilateral pleural effusions. Ultrasonographic evidence of plasma leakage may be detected in some cases within 3 days after fever onset. Pleural effusion is the most common ultrasonographic sign of plasma leakage (62% of DHF cases 1 day after defervescence). Thickening of the gallbladder wall, postvesicular edema, and ascites are detected less frequently and resolve more rapidly than pleural effusions.[153] Approximately 10 percent of patients have gross ecchymosis or gastrointestinal bleeding. During the transition from the febrile to the critical phase, it is crucial for the clinician to be aware of warning signs of impending vascular permeability: persistent vomiting, increasingly severe abdominal pain, rising hematocrit, and falling platelet count. After a 24- or 36-hour period of crisis, convalescence is fairly rapid in children who recover. The temperature may return to normal before or during the stage of shock.

PATHOLOGY AND PATHOGENESIS

In rhesus monkeys experimentally infected with dengue virus by subcutaneous inoculation, virus replicates initially in the skin. Virus disseminates rapidly to regional lymph nodes and then to lymphatic tissue throughout the body.[109] Early in the viremic period, virus can be recovered only from the skin inoculation site and lymph nodes, whereas 2 to 3 days later, evidence of general dissemination to skin and other tissues is found. Virus is recovered from the skin, lymph nodes, and several leukocyte-rich tissues for up to 3 days after termination of viremia. Virus can be recovered from circulating leukocytes and from the skin only at the end of the viremic period. The number of sites from which virus can be recovered increase as the infection progresses. Intracellular infection is terminated abruptly 2 to 3 days after viremia ceases.

Monkeys infected initially with dengue viruses 1, 3, or 4 and then with dengue virus 2 had higher viremia than when the same strain was inoculated into susceptible animals.[60,63] A similar phenomenon was observed in monkeys given diluted dengue antibodies and then challenged with dengue virus 2.[58] This phenomenon, in vivo antibody-dependent enhancement of dengue infection, provides an explanatory hypothesis of the immunopathogenesis of dengue in humans.

Models have been developed in mice that lack interferon (INF) receptors in which early infection events result in severe vascular permeability.[186,190] Of importance, dengue antibodies modulate infection in Fc-receptor–bearing cells all the way from protection to enhancement.[8,9,189] To date, mutant dengue virus 2 is required to produce DHF-like disease in immunocompromised mice

after peripheral or intravenous infection. These mutations affect replication or infection efficiency. A single amino acid change in NS4B modulates replicative efficiency, and two amino acid changes in the envelope protein affect interactions with heparan receptors for dengue infection.[45,124] The operative correlate of vascular permeability is the inoculum dose. Enhancing antibodies increase viremia and disease severity when infection is established using a low dose.

If tissue cultures or suckling mice are used for recovery of virus, dengue usually is absent in tissues at the time of death.[117] If patients experienced a second dengue infection, their tissue suspensions contain large quantities of dengue-neutralizing antibodies. The use of mosquito inoculation techniques improves viral isolation rates.[134,136,157] Genetic probes increase viral detection sensitivity still further.[80] In humans, dengue viruses infect and replicate efficiently in intracutaneous Langerhans cells in vitro and in tissue explants.[185] Virus ultimately targets liver parenchymal cells, where infection produces apoptosis, but hepatocytes may not serve as replicative hosts.[80,110] Late in infection, virus is found associated in circulating monocytes.[40] Fluorescent antibody, virus isolation, electron-microscopic, and in situ hybridization studies suggest tissue mononuclear phagocytes as major infection hosts.[8,15,60,70,85]

On pathologic examination, usually no gross or microscopic lesions are found that might account for death.[15] In rare instances, death may be caused by gastrointestinal or intracranial hemorrhage. Minimal to moderate hemorrhage is seen in the upper gastrointestinal tract, and petechial hemorrhage occurs frequently in the intraventricular septum of the heart, on the pericardium, and on the subserosal surfaces of major viscera. Focal hemorrhaging is seen occasionally in the lungs, liver, adrenals, and subarachnoid space. The liver usually is enlarged, often with fatty changes. Yellow, watery, at times blood-tinged effusions are present in serous cavities in approximately three fourths of patients. Retroperitoneal tissues are markedly edematous.

On microscopic examination, perivascular edema in soft tissues and widespread diapedesis of red blood cells can be seen. Maturational arrest of megakaryocytes may be noted in the bone marrow,[96] and increased numbers of such megakaryocytes are seen in the capillaries of the lungs, in the renal glomeruli, and in the sinusoids of the liver and spleen. Proliferation of lymphocytoid and plasmacytoid cells, lymphocytolysis, and lymphophagocytosis occur in the spleen and lymph nodes.[14] In the spleen, evidence shows infected tissue macrophages and malpighian corpuscle germinal centers are necrotic.[7,112] Depletion of lymphocytes occurs in the thymus. In the liver, widespread evidence of infection with varying degrees of fatty metamorphosis, focal midzonal necrosis, and hyperplasia of Kupffer cells present.[7,14,84] Dengue infection of hepatocytes may result in apoptosis, with evidence of assembled virions lacking.[84,110] Non-nucleated cells with vacuolated acidophilic cytoplasm resembling Councilman bodies (apoptotic hepatocytes[80] are seen in the sinusoids. A mild, proliferative glomerulonephritis is present. Biopsy specimens of the rash reveal swelling and minimal necrosis of endothelial cells, subcutaneous deposits of fibrinogen, and, in a few cases, dengue antigen in extravascular mononuclear cells and on blood vessel walls.[20]

Epidemiologic, clinical, and virologic studies of DHF/DSS in humans have shown a significant association between severe vascular permeability and dengue virus infection in the presence of circulating dengue antibody, whether it is passively acquired from the mother or actively acquired from previous infection. Risk for developing vascular permeability syndrome is inversely correlated with age; the youngest children are at highest intrinsic risk.[4,52] In humans, circulating antibody appears to have two biologic activities: neutralization of virus and enhancement of infection.[61,63] In Thailand and Vietnam, DHF/DSS developed in infants during dengue virus type 2 infection only when maternal neutralizing antibody had catabolized to low titer[27] and infection-enhancing antibodies were left in circulation.[72,92,114,149] Similarly, in a prospective study of dengue virus infection in Thai children, DHF/DSS occurred in children who had circulating enhancing antibodies from a previous single dengue virus infection, but it did not occur in children whose first infection left them with low levels of cross-reactive dengue virus type 2 neutralizing antibody at the time of the second dengue virus infection.[93] A similar mechanism explains the failure of secondary infections to produce DHF/DSS with the American genotype dengue type 2.[171] American genotype dengue 2 viruses are significantly neutralized by human anti–dengue 1, whereas Southeast Asian dengue 2 viruses are not.[94] The full-length sequences of the American and Southeast Asian dengue 2 genomes reveal few amino acid differences.[102]

In vitro studies of dengue virus type 2 demonstrated enhanced growth in cultures of human mononuclear phagocytes that were supplemented with very small quantities of dengue antibodies.[69] Dengue infection of primary human monocytes or macrophages by enhancing immune complexes increased infection productivity by 100-fold.[19] Infection of human myeloid cells by dengue virus–immunoglobulin (Ig)G antibody complexes appears to suppress innate immunity via type I INF or an alternative mechanism involving interleukin (IL)-10.[26,162] Investigators have proposed that the infected mass of mononuclear phagocytes in dengue-infected humans circulating enhancing antibodies, whether passively or actively acquired, is greater than in nonimmune individuals.[56,61,63,66] In serial blood samples taken early in the illness in children experiencing secondary dengue infections, enhanced viremia levels or enhanced levels of dengue NS1 predicted severe disease.[104,168] Because of its late appearance, vascular permeability is thought to result when infected cells are attacked by activated T lymphocytes with the release of vasoactive cytokines.[61,138] As yet, no cytokine or group of cytokines is the proved cause of vascular permeability, although blockade of tumor necrosis factor (TNF-α) prevents vascular permeability in a mouse model.[9] The reduced risk for DHF/DSS in protein-calorie malnourished children[158] and the increased risk for DHF/DSS in girls versus boys are consistent with the hypothesis that a competent immune elimination

system must be available to generate the mediators of DHF/DSS.[5,116]

Evidence indicates the existence of a human dengue resistance gene. Epidemiologic studies of the 1981 Cuban outbreak demonstrated a higher risk for DHF/DSS in white than in black individuals.[51,95] A search for DHF/DSS in black children in Haiti revealed no cases, despite the presence of high dengue type 1, 2, and 4 infection rates and circulation of the Southeast Asian genotype dengue 2 viruses.[73] Human leukocyte antigens and other genetic factors have shown differing frequencies in DHF/DSS cases and controls.[28,150] Early in the acute stage of secondary dengue virus infection, rapid activation of the complement system occurs.[18,182] During shock, blood levels of C1q, C3, C4, C5, C6, C7, C8, and C3 proactivators are depressed and C3 catabolic rates are elevated. The blood clotting and fibrinolytic systems are activated.[177,180] As yet, neither the mediator of vascular permeability nor the complete mechanism of bleeding has been identified unequivocally. The kinin system apparently is not involved. Recent studies suggest a role for TNF, IL-2, and INF-γ.[96,139] Capillary damage allows fluid, electrolytes, protein, and, in some instances, red blood cells to leak into intravascular spaces.[179] This internal redistribution of fluid, together with deficits caused by fasting, thirsting, and vomiting, results in hemoconcentration, hypovolemia, increased cardiac work, tissue hypoxia, metabolic acidosis, and hyponatremia. A mild degree of disseminated intravascular coagulation, plus liver damage and thrombocytopenia, could contribute additively to produce hemorrhage.[150]

TABLE 175D-1 WHO 1997 Case Definition for Dengue Hemorrhagic Fever and Dengue Shock Syndrome[183]

Dengue hemorrhagic fever (DHF):
- Fever, or history of acute fever, lasting 2 to 7 days, occasionally biphasic
- Hemorrhagic tendencies, evidenced by at least one of the following:
  - A positive tourniquet test
  - Petechiae, ecchymosis, or purpura
  - Bleeding from the mucosa, gastrointestinal tract, injection sites, or other locations
  - Hematemesis or melena
- Thrombocytopenia (100,000 cells per mm^3 or less)
- Evidence of plasma leakage due to increased vascular permeability, manifested by at least one of the following:
  - A rise in the hematocrit equal to or greater than 20% above average for age, sex, and population
  - A drop in the hematocrit following volume replacement treatment equal to or greater than 20% of baseline
  - Signs of plasma leakage such as pleural effusion, ascites, and hypoproteinemia

Dengue shock syndrome (DSS):

All of the above four criteria for DHF must be present and evidence of circulatory failure manifested by the following:
- Rapid and weak pulse, and
- Narrow pulse pressure (<20 mm Hg) or manifested by:
- Hypotension for age, and
- Cold, clammy skin and restlessness

WHO, World Health Organization.

DIAGNOSIS

Dengue Fever

A clinical diagnosis can be made by having a high index of suspicion and knowledge of the geographic distribution and ecology of dengue viruses. Activities of the patient during the period preceding the onset of illness may give important clues to the possibility of infection.

The differential diagnosis includes many viral, respiratory, and influenza-like diseases and the early stages of malaria, typhoid fever, scrub typhus, hepatitis, and leptospirosis. Abortive forms of these diseases may never evolve beyond a dengue-like stage. Four arbovirus diseases are similar to dengue: chikungunya and o'nyong-nyong fever (togaviruses), West Nile fever (flavivirus), and Oropouche (bunyavirus). Four other diseases are dengue-like but without rash: Colorado tick fever, sandfly fever, Ross River fever, and the mild form of Rift Valley fever. Because of the variation in clinical findings and the multiplicity of possible causative agents, the descriptive term *dengue-like disease* should be used until a specific etiologic diagnosis is provided by the laboratory.

Dengue Hemorrhagic Fever/Dengue Shock Syndrome/Severe Dengue

DHF is a dengue illness syndrome in which an acute fever is accompanied by thrombocytopenia (<100,000/mm^3), prolonged bleeding time, elevated activated partial thromboplastin time, and hemoconcentration (hematocrit >20% of the recovery value).[33,154,155] For case diagnostic criteria, see Table 175D-1. Early detection of vascular permeability remains a diagnostic problem; however, the use of strain-gauge plethysmography documents up to 50 percent higher microvascular permeability in DHF/DSS patients than in controls.[14] Pleural or peritoneal effusions observed by ultrasonography or radiography are virtually pathognomonic.[153] DSS is diagnosed when these manifestations are accompanied by hypotension or narrow pulse pressure (<20 mm Hg). In areas endemic for dengue, hemorrhagic fever should be suspected in children with a febrile illness who exhibit shock and hemoconcentration with thrombocytopenia. Hypoproteinemia, hemorrhagic manifestations, and hepatic enlargement are frequent accompanying findings. Because many rickettsial diseases, meningococcemia, and other severe illnesses caused by a variety of agents may produce a similar clinical picture, the diagnosis should be made only when epidemiologic or serologic evidence suggests the possibility of dengue. Hemorrhagic manifestations have been described in other diseases of viral origin, including the arenavirus hemorrhagic fevers of Argentina, Bolivia, and West Africa (Lassa fever); the tick-borne hemorrhagic fevers of India and the former Soviet Union; hemorrhagic fever with renal syndrome, which occurs across northern Eurasia, specifically from Scandinavia to Korea; and Marburg and Ebola virus infections in central Africa.[86]

TABLE 175D-2 WHO 2009 Dengue Case Definitions

Probable dengue:

Live in or travel to dengue-endemic area, fever, and two of the following:

- Nausea, vomiting
- Rash
- Aches and pains
- Positive tourniquet test
- Leucopenia
- Any "warning sign"

Dengue with warning signs:

- Abdominal pain or tenderness
- Persistent vomiting
- Clinical fluid accumulation
- Mucosal bleed
- Lethargy, restlessness
- Liver enlargement >2 cm
- Laboratory increase in HCT concurrent with rapid decrease in platelet count

Severe dengue (short form):

- Severe plasma leakage
  - Shock (DSS)
  - Fluid accumulation with respiratory distress
- Severe bleeding (as evaluated by clinician)
- Severe organ involvement
  - Liver AST or ALT ≥1000
  - CNS-impaired consciousness
  - Heart and other organs

Severe dengue (long form):

- There is evidence of plasma leakage, such as the following
  - High or progressively rising hematocrit
  - Pleural effusions or ascites
  - Circulatory compromise or shock (tachycardia, cold and clammy extremities, capillary refill time greater than 3 seconds, weak or undetectable pulse, narrow pulse pressure, or, in late shock, unrecordable blood pressure)
- There is significant bleeding
- There is an altered level of consciousness (lethargy or restlessness, coma, convulsions)
- There is severe gastrointestinal involvement (persistent vomiting, increasing or intense abdominal pain, jaundice)
- There is severe organ impairment (acute liver failure, acute renal failure, encephalopathy or encephalitis, or other unusual manifestations, cardiomyopathy) or other unusual manifestations.

ALT, alanine aminotransferase; *AST,* aspartate aminotransferase; *CNS,* central nervous system; *DSS,* dengue shock syndrome; *HCT,* hematocrit;

Severe Dengue

In 2009, the WHO released *Dengue: Guidelines for Diagnosis, Treatment, Prevention and Control.*[184] New case definitions were promulgated for use by clinicians and public health workers. These were intended to reduce the diagnostic requirement on laboratory studies.[183] The earlier and new WHO case definitions are listed in Tables 175D-1 and 175D-2, respectively. A useful focus of the new case definitions is the effort to alert clinicians to recognize the clinical signs of dengue vascular permeability (Dengue with Warning Signs). However, the clinical category Severe Dengue includes patients with altered levels of consciousness, severe liver disease, acute renal failure, cardiomyopathy, respiratory distress, and severe bleeding. Many of these may accompany prolonged shock or are due to comorbidity. Severe bleeding, however, does accompany dengue infections in 10 to 15 percent of cases. Particularly severe is gastrointestinal bleeding in adults with peptic ulcer disease. Treatment may require surgical intervention and aggressive replacement of blood losses. But, these patients may not have increased vascular permeability. Labeling patients who are experiencing fluid loss and blood loss shock using the same diagnostic term could lead to errors in diagnosis and management. More serious is using Severe Dengue to identify patients who are accumulating fluid and are in respiratory distress. This may confuse a common iatrogenic complication caused by excess intravenous fluid treatment with the vascular permeability shock syndrome. The new case definitions were designed to facilitate triage and better management of dengue patients, an assertion that has resulted in vigorous debate.[11,12,113,155]

LABORATORY STUDIES

An etiologic diagnosis can be made by serologic study of properly collected serum samples, by isolation of the virus, and by identification of viral RNA or the nonstructural protein NS1 in acute-phase sera.[52,121,122] The acute-phase serum or plasma collected for isolation of virus should be stored optimally at less than 65° C (149° F). Serologic diagnosis depends on a fourfold or greater increase in antibody titer by hemagglutination inhibition, complement fixation, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), or neutralization. IgM capture ELISA has revolutionized dengue serology, and commercial kits are available.[17,82,83] Primary and sequential (secondary) dengue virus infections result in the production of dengue-reactive IgM antibodies, which appear during the acute phase and disappear within 60 days of infection.[83] Secondary or primary dengue virus infections can be confirmed in a single serum specimen by quantitating IgM/IgG antibody ratios. IgG antibody concentrations are abundant in secondary but minimal in primary dengue virus infection. Dengue NS1 proteins can be detected in blood during the acute illness phase by dengue group–specific antibodies, and these have been formatted into commercial ELISA or rapid immunochromatographic tests.[16,43] By combining IgM-capture ELISA and NS1 detection, point-of-care tests are available to diagnose acute dengue infections. Accurate use of diagnostic tests requires an understanding of the kinetics of primary and secondary dengue virus infections. Dengue IgM antibodies are seldom detected until 5 or more days after onset of fever. By contrast, dengue NS1 protein circulates in blood during and shortly after febrile period, with higher detection in primary and secondary dengue infections.[16,17,81]

Numerous techniques are available for the recovery and identification of dengue viruses.[184] Recommendations for general use have been made by a WHO expert committee.[184] Diagnostic testing for dengue virus infection is available through commercial reference laboratories, selected public health laboratories, and the Dengue Branch of the Centers for Disease Control and

Prevention (http://www.cdc.gov/dengue). Acute-phase serum, mosquito suspensions, or other materials thought to contain dengue virus may be inoculated into suckling mice, which may be examined for sickness or subtle neurologic signs or challenged at 14 days with a neurovirulent dengue virus. Repeated subpassage markedly increases the neurovirulence of dengue virus. Alternatively, materials may be inoculated into any of several tissue cultures of mammalian or mosquito origin and examined for plaques under agar or methylcellulose overlay, for cytopathic effect, resistance to a challenge cytopathic virus by use of a fluid overlay, or fluorescence or other markers with the use of an appropriate detection system. Intrathoracic inoculation of *A. albopictus*, *A. aegypti*, or *Toxorhynchites* spp. is a highly sensitive dengue virus recovery system.[134,135]

TREATMENT

Dengue Fever

Treatment is supportive. Bed rest is advised during the febrile period. Antipyretics or cold sponging should be used to keep the body temperature below 40° C (104° F). Paracetamol (10 to 15 mg/kg every 4 to 6 hours) is the preferred antipyretic agent. Analgesics or mild sedation may be required to control pain. Fluid and electrolyte replacement therapy is required when deficits caused by sweating, fasting, thirsting, vomiting, or diarrhea are present. Because of the risk for Reye syndrome and the dengue hemorrhagic diathesis, aspirin should not be given to reduce fever or to control pain. Adult patients may develop severe menorrhagia or gastrointestinal bleeding during acute dengue fever. Treatment may require blood transfusions and, in the case of peptic ulcer disease, surgical intervention.

Dengue Hemorrhagic Fever (Compensated Shock)/Dengue Shock Syndrome

Explicit recommendations for management of DHF (compensated shock) and DSS have been made by a WHO expert committee.[184] These and research observations are the basis of this section.[33,38,178]

Outpatients

No specific antiviral treatment exists, but in DHF/DSS, symptomatic and supportive measures are effective.

The major pathophysiologic abnormality seen in DHF/DSS is an acute increase in vascular permeability that leads to leakage of fluid and albumin. Plasma volume studies revealed a reduction of more than 20 percent in severe cases. Supporting evidence of plasma leakage (and consequent hypovolemia) includes a rapid, weak pulse; diaphoresis; cool, pale skin of the extremities; decreased urine output; and direct measurement by strain-gauge plethysmography,[14] pleural effusion on chest radiography or ultrasonography, hemoconcentration, and hypoproteinemia. Pleural effusion may not be evident until after fluid resuscitation is started. In the absence of increased vascular permeability, clinically significant hemoconcentration may result from thirst, dehydration, fever, anorexia, and vomiting. Fluid intake by mouth should be as ample as tolerated. Electrolyte and dextrose solution (as used in diarrheal disease), fruit juice, or both are preferable to plain water. With high fever, a risk for seizures exists, so antipyretic drugs may be indicated. Salicylates should be avoided because they are known to cause bleeding and acidosis. Acetaminophen is preferable at the following doses: younger than 1 year, 60 mg per dose; 1 to 3 years of age, 60 to 120 mg per dose; 3 to 6 years of age, 120 mg per dose; and 6 to 12 years of age, 240 mg per dose.

Children should be observed closely for early signs of shock. The critical period is the transition from the febrile to the afebrile phase. Frequent hematocrit determinations are essential because they reflect the degree of plasma leakage and the need for administration of intravenous fluid. Hemoconcentration usually precedes changes in blood pressure and pulse. The hematocrit should be determined daily from the third day until the temperature becomes normal for 1 or 2 days. Patients who tolerate oral fluids and pass urine at least once in 6 hours should be sent home, but instructed to return with onset of any warning sign. Patients should be clinically monitored until after defervescence. Patients with social situations not permitting observation and those living alone or far from clinical facilities may be admitted for observation.

- Oral or parenteral fluid therapy can be administered in an outpatient rehydration unit for correction of dehydration or acidosis or when signs of hemoconcentration are present. The volume of fluid and its composition are similar to the fluids used for the treatment of diarrhea with moderate dehydration. The fluids should consist of the following:
- One third to half of the total fluid as physiologic saline solution.
- Half to two thirds of the remainder as 5 percent glucose in water.
- For acidosis: One fourth of the total fluids should be one-sixth molar sodium bicarbonate.
- Solution for fluid therapy in DHF: Lactated Ringer solution, 5 percent glucose in half normal physiologic saline solution, 5 percent glucose in one half lactated Ringer solution, 5 percent glucose in one-third physiologic saline solution.
- Fluids as listed are calculated to be given during a 24-hour period. If the child seems severely dehydrated, half the calculated fluid is given in the first 8 hours and the second half in the next 16 hours. During rapid administration of fluids, watching for signs of cardiac failure is especially important.

Written orders should be explicit about the type of solution and the rate of administration.

Inpatients

Patients should be hospitalized and immediately treated when they have any of the following signs and symptoms

of shock: restlessness or lethargy, cold extremities and circumoral cyanosis, rapid and feeble pulses, narrowing of pulse pressure (<20 mm Hg) or hypotension, and sudden rise in hematocrit or continuously elevated hematocrit despite the administration of intravenous fluid.

Shock is a medical emergency and requires access to intensive care facilities if available. A baseline hematocrit should be obtained. Immediate administration of intravenous fluid to expand plasma volume is essential. In children, shock may develop or subside during the course of a 48-hour period, so close observation 24 hours per day is imperative. Patients with similar degrees of severity should be grouped together. Those with shock require intensive 24-hour care by nurses and physicians. Paramedical workers or parents can assist in provision of oral fluid therapy or in surveillance of the rate of intravenous fluid administration and general status of the patient. Critical care management of dengue vascular permeability syndrome is a major challenge to pediatricians who care for more than half the world's children; therefore, detailed guidelines, including recognition and management of hemorrhage and of fluid overload (an all too frequent complication and cause of death), are given in the following section.

Treatment of Patients with Nonshock Dengue Hemorrhagic Fever (Compensated Shock). Treatment for patients with nonshock dengue hemorrhagic fever is as follows:

- Start intravenous fluid resuscitation with isotonic crystalloid solution at 5 to 10 mL/kg/hr over 1 hour. Then reassess the patient's condition (i.e., vital signs, capillary refill time, hematocrit, urine output).
- If the patients' condition improves, intravenous fluids should be gradually reduced to 5 to 7 mL/kg/hr for 1 to 2 hours, then to 3 to 5 mL/kg/hr for 2 to 4 hours, and then to 2 to 3 mL/kg/hr and then further depending on hemodynamic status.
- If vital signs are still unstable, check hematocrit after first bolus. If the hematocrit increases or is still high (>50%), administer a second bolus of crystalloid solution at 10 to 20 ml/kg/hr for 1 hour. After the second bolus, if there is improvement, reduce the rate to 7 to 10 mL/kg/hr for 1 to 2 hours. If the hematocrit decreases from the initial reference hematocrit, this indicates bleeding. Immediately obtain cross match and transfuse blood.
- Further boluses of crystalloid solutions may be necessary for the next 1 to 2 days.

Treatment of Patients with Shock. Treatment for patients with shock is as follows:

- For patients with narrow pulse pressure or systolic hypotension, initiate intravenous fluid resuscitation with crystalloid or colloid (gelatin has the least effect on blood coagulation, dextran 40 and 70 are in wide use) solution at 20 mL/kg as a bolus over 15 minutes to bring the patient out of shock as quickly as possible.
- If the patient's condition improves, give a crystalloid/colloid infusion of 10 mL/kg/hr for 1 hour. Then continue with crystalloid infusion and gradually reduce to 5 to 7 mL/kg/hr for 1 to 2 hours, then to 3 to 5 mL/kg/hr for 2 to 4 hours, and then to 2 to 3 mL/kg/hr or less, which can be maintained for up to 24 to 48 hours.
- If vital signs are still unstable, review the hematocrit obtained before the first bolus. If the hematocrit is low, this indicates bleeding and the need for blood transfusion.
- If the hematocrit was high in contrast to the baseline value, change intravenous fluids to colloid solutions at 10 to 20 mL/kg/hr as a second bolus given over 30 minutes to 1 hour. After the second bolus, reassess the patient. If the condition improves, reduce the rate to 7 to 10 mL/kg/hr for 1 to 2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned earlier. If the condition is still unstable, repeat the hematocrit after the second bolus.
- If hematocrit decreases from the previous value, this indicates bleeding and the need for blood transfusion. If the hematocrit increases from the previous value or remains very high, continue colloid solutions at 10 to 20 mL/kg/hr as a third bolus over 1 hour. After this dose, reduce the rate to 7 to 10 mL/kg/hr for 1 to 2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned earlier.
- Further boluses may need to be given during the next 24 hours. The rate and volume of each bolus infusion should be titrated to the clinical response.

General Management. If resources permit, patients with severe shock syndrome should have an arterial catheter placed. The reason for this is that in shock states, estimation of blood pressure using a cuff is commonly inaccurate. An indwelling arterial catheter allows for continuous and reproducible blood pressure measurements and frequent blood sampling on which decisions regarding therapy can be made. Monitoring of electrocardiogram and pulse oximetry should be available. Urine output should be checked regularly (i.e., hourly until patient is out of shock, then every 1 to 2 hours. Hematocrit should be monitored before and after fluid boluses until stable and then every 4 to 6 hours. In addition, there should be monitoring of arterial or venous blood gases, lactate, total carbon dioxide/bicarbonate every 30 minutes to 1 hour until stable, and blood glucose before fluid resuscitation and afterward as indicated.

Treatment of Hemorrhagic Complications

- Patients in danger of bleeding are those with prolonged or refractory shock, hypotensive shock and renal or liver failure or persistent metabolic acidosis; those who were given nonsteroidal anti-inflammatory agents; those with preexisting peptic ulcer disease; those who are on anticoagulant therapy; and those who have any form of trauma, including intramuscular injections. Patients with hemolytic conditions are at risk for acute hemolysis with hemoglobinuria and will require blood transfusion.
- Severe bleeding can be recognized by refractory shock that fails to respond to consecutive fluid

resuscitation of 40 to 60 mL/kg, hypotensive shock with low or normal hematocrit before fluid resuscitation, or persistent or worsening metabolic acidosis despite well-maintained systolic blood pressure, especially if accompanied by severe abdominal tenderness and distention.
- Give 5 to 10 mL/kg of fresh-packed red cells or 10 to 20 mL/kg of fresh whole blood at an appropriate rate and observe the clinical response.
- Consider repeating the blood transfusion if there is further blood loss or no appropriate rise in hematocrit after blood transfusion.
- There are no evidence-based data supporting the use of platelet concentrates or fresh-frozen plasma as a treatment for profound thrombocytopenia or severe bleeding. This treatment option is widely practiced in dengue-endemic countries and may contribute to fluid overload.

Recognizing Fluid Overload Begins with Knowing When to Decrease or Stop Intravenous Fluids. Intravenous fluids should be discontinued or reduced when there are signs of cessation of plasma leakage; stable blood pressure, pulse, and peripheral perfusion; hematocrit decreases in the presence of good pulse volume; no fever for more than 24 to 48 hours; resolving bowel and abdominal symptoms, and improving urine output.

Causes of fluid overload are excessive or too rapid intravenous fluids; incorrect use of hypotonic rather than isotonic crystalloid solutions; inappropriate use of large volumes of intravenous fluids in patients with unrecognized severe bleeding; inappropriate transfusion of fresh-frozen plasma, platelet concentrates or cryoprecipitates; continuation of intravenous fluids after plasma leakage has stopped; and comorbid conditions, such as congenital or ischemic heart disease and chronic lung or renal disease.

Early clinical features of fluid overload are respiratory distress, difficulty in breathing, rapid breathing, chest wall in-drawing, wheezing (rather than crepitations), large pleural effusions, tense ascites, and increased jugular venous pressure.

Late clinical features are pulmonary edema (cough with pink or frothy sputum with or without crepitations; irreversible shock (i.e., heart failure with ongoing hypovolemia); chest radiograph shows cardiomegaly, pleural effusion, upward displacement of the diaphragm by the ascites, and varying degrees of "bat wings" appearance with or without Kerley B lines suggestive of fluid overload and pulmonary edema.

Action Plan for Treatment of Fluid Overload. Treatment of fluid overload is as follows:
- Oxygen therapy should be given immediately.
- Stop intravenous fluids.
- Check physiologic status: ECG to exclude ischemic changes and arrhythmia; arterial blood gases; echocardiogram for assessment of left ventricular function and regional wall dyskinesia that may suggest underlying ischemic heart disease; and cardiac enzymes.
- If necessary, give oral or intravenous furosemide 0.1 to 0.5 mg/kg/dose once or twice daily, or a continuous infusion of furosemide 0.1 mg/kg/hr. Monitor serum potassium and correct the ensuing hypokalemia.
- Patients in shock with low or normal hematocrit levels but who show signs of fluid overload may have occult hemorrhage. Further infusion of large volumes of intravenous fluids will lead only to a poor outcome. Careful transfusion of fresh whole blood should be initiated as soon as possible. Repeated small boluses of colloid solution may be helpful.

REGULATORY MEASURES

Dengue diseases are not subject to international quarantine or surveillance regulations. Dengue is a nationally notifiable disease in the United States and suspected cases should be reported to the local health department. An intensive and effective voluntary reporting system has been devised by the regional offices of the WHO. People traveling to areas where dengue is endemic should assess the risk (http://www.healthmap.org/dengue/) and take necessary precautions to protect themselves against mosquito exposure.

PROGNOSIS

Not all patients suspected of having DHF need to be hospitalized because circulatory failure and shock may develop in only approximately a third of patients. Mild and moderate cases may be treated on an outpatient basis. For the purpose of early recognition of shock, parents should be advised to bring the patient back if evidence of clinical deterioration is noted or such warning signs as restlessness with or without lethargy, severe abdominal pain, cold extremities, and skin congestion occur on or after the third day after the onset of fever.

In most cases, early and effective replacement of lost plasma with plasma, plasma expanders, or fluid and electrolyte solutions (or any combination of these products) results in a favorable outcome. The acute onset of shock and the rapid, often dramatic clinical recovery, together with the fact that no destructive or inflammatory vascular lesions are observed, suggest that the disease is produced by transient functional vascular changes caused by short-acting pharmacologic mediators.

Sequelae in dengue and DHF have not been studied systematically. Common sequelae of mild and uncomplicated dengue virus infection include bradycardia and ventricular extrasystoles during the convalescent stage, often persisting for several weeks. Profound asthenia with or without mental depression has been described. In patients with DHF/DSS, great care must be taken to reduce use of invasive procedures for managing shock. Nosocomial infections such as gram-negative sepsis can masquerade as DHF/DSS. Overhydration during the shock resuscitation phase may lead to heart failure and a complicated,

stormy postshock stage. Infrequently, residual brain damage occurs, apparently as a result of either prolonged shock or, occasionally, intracranial hemorrhage. Children in whom profound shock develops rapidly with no detectable diastolic pressure or with unobtainable blood pressure, children in shock with delayed admission to the hospital, or children in shock with gastrointestinal hemorrhage have a poor prognosis. Mortality rates may exceed 50 percent in these groups.

PREVENTION

Three safe and immunogenic tissue culture–based vaccines for dengue virus types 1, 2, 3, and 4 are in phase II or III human clinical trials, one of which is nearing licensure.[39,50,120,159,169] The lead candidate, manufactured by Sanofi Pasteur, is a chimera of the nonstructural genes of yellow fever 17D vaccine spliced with structural genes of the four dengue viruses.[49] It is designed as a three-dose vaccine to be given at months 0, 6, and 12. At present, prophylaxis depends on killing vector mosquitoes or avoiding mosquito bites. This involves the use of insecticides, repellents, protective body clothing, and screens on houses to avoid mosquito bites. Destruction of *A. aegypti* breeding sites also is effective.[184] If water storage is mandatory, a tight-fitting lid or a thin layer of oil may prevent eggs from being deposited or hatching. A larvicide such as temefos (Abate), which is available as a 1 percent sand granule formulation and effective at a concentration of 1 ppm, may be added safely to drinking water.

Epidemic Measures

The WHO recommends integrated vector management, which requires training, preparation, and application of appropriate technologies.[184] Control of *A. aegypti* is mainly achieved by eliminating container habitats that are favorable oviposition sites permitting development of aquatic stages. In emergencies, space sprays can be applied either as thermal fogs at 10 to 50 L/ha or as ultra-low-volume applications of undiluted or slightly diluted technical-grade insecticide in the form of a cold aerosol or droplets of controlled size (15 to 25 μm) at a rate of 0.5 to 2.0 L/ha. Portable or vehicle-mounted thermal or cold-fog generators can be used for ground application. If the target area exceeds 1000 ha or cannot be covered for ground equipment within 10 days, aerial cold fog application is sometimes used. Applications vary with the susceptibility of the target species and environmental conditions, such as wind speed. Cold-fog applications from large fixed-wing aircraft are made at approximately 240 km/h and 60 m above the ground.

Eradication and Control

A. aegypti was eradicated successfully from countries and whole continents with use of the techniques pioneered by the Rockefeller Foundation in its worldwide program to control urban yellow fever.[156] With time, the species successfully reestablished itself in much of its former range. An eradication campaign in the United States was abandoned and replaced by a program of disease surveillance and containment of introduced virus.

Mosquito control or eradication programs require the simultaneous use of two approaches: a reduction in breeding sites and the application of larvicides. Alternatively, a significant reduction in population may be effected by closely spaced applications of adulticide.[46]

Source reduction requires public support by either legal sanctions or voluntary actions (see the following section). Source reduction campaigns should be well organized, supervised, and evaluated. Proper disposal of discarded cans, bottles, tires, and other potential breeding sites not used for storage of drinking or bathing water should be performed. Sides of water storage containers should be scrubbed to remove eggs when the water level is low. Water storage containers for drinking and bathing and flower vases should be emptied completely once weekly. Water containers that cannot be emptied should be treated with Abate 1 percent sand granules at a dosage of 1 ppm (e.g., 10 g of sand to 100 L of water). Treatments should be repeated at intervals of 2 to 3 months.

Vehicle-mounted or portable ultra-low-volume aerosol generators or mist blowers can be used to apply technical-grade malathion or fenitrothion at 438 mL/hectare. Three applications made at 1-week intervals can suppress *A. aegypti* populations for approximately 2 months.

In dengue-endemic countries, little effort has been made to adopt building codes or waste collection methods to reduce the number of mosquito breeding sites.[101] Furthermore, almost no way has been found to use the private sector to implement vector control despite ample evidence of long-term successful programs in the United States.[25,32]

A new generation of vector control strategies is under active development and testing. *Mesocyclops*, an antilarval insect predator, has been introduced into water storage containers in rural Vietnam with near eradication of *A. aegypti* larvae.[89,90,152,169] Infection of *A. aegypti* by *Wolbachia*, a species of rickettsial-like organism, blocks replication of dengue virus and vectoral capacity of the mosquito.[112] *Wolbachia* has been successfully introduced into wild populations of *A. aegypti* with sufficient spread to prevent dengue transmission.[77] Various methods of achieving and spreading sterile *A. aegypti* males or flightless females are being tested in the field.[44,75,181]

Health Education

Control of *A. aegypti* has been maintained effectively in some tropical areas through the simple expedient of emptying water containers once per week. During the yellow fever campaigns, strong sanitary laws made the breeding of mosquitoes on premises a crime punishable by fine or jail.[156] In the modern era, Singapore and Cuba have adopted these measures with moderate degrees of success.[119] Health education through mass media and schools has been attempted in Myanmar, Thailand, Malaysia, and Indonesia, but without spectacular success.[37] The goals of health education and community

participation approaches are to make the population aware of the identity of the vector of DHF, to describe its biting habits (daytime feeding) and its breeding habits (containers holding clean water), and to motivate people to reduce breeding sources by emptying water from containers on a regular basis.[62] The use of piped water rather than water storage should be encouraged. Studies in Malaysia after the 1973 epidemic of DHF indicated a very low level of functional knowledge among the inhabitants of Kuala Lumpur, Malaysia, about the vector of DHF.[37] Discouragingly, persons who were informed correctly, in most instances, took no action to protect themselves against mosquito breeding in their homes. Extensive effort is being made to apply social science methods to gain the voluntary participation of the population in sustained mosquito control programs.[106]

175E ■ JAPANESE ENCEPHALITIS

Theodore F. Tsai

Japanese encephalitis (JE), a mosquito-borne flaviviral infection, is the leading vaccine-preventable viral encephalitis in Asia.

HISTORY

JE first was recognized after an outbreak in Japan in 1924 led to an alarming 6125 cases of encephalitis. In retrospect, similar summer and autumn outbreaks were recognized as early as 1871 to 1873.[37] In 1933, Hayashi recovered the virus from monkeys and the brain of a patient, and in 1938, Mitamura confirmed its mosquito-borne mode of transmission by isolating the virus from *Culex tritaeniorhynchus*. Inactivated vaccine prepared from infected mouse brain was licensed in Japan in 1956, and its use successfully controlled the disease in Asian countries where it was deployed. New inactivated cell culture–derived and live attenuated vaccines are now displacing the efficacious but reactogenic 50-year-old mouse brain–derived product.[29]

ETIOLOGIC AGENT

JE virus is the prototypic member of the flaviviral antigenic complex that includes St. Louis encephalitis, Murray Valley encephalitis, and West Nile viruses. Five viral genotypes have been described. Within the last 3 decades, viruses in genotype I have displaced previously predominant genotype III strains and genotype V viruses also may be emerging.[14,15,49,68,95] Because humans are incidental to the viral transmission cycle, the changing distribution of viral genotypes indicates evolving viral adaptation to vertebrate hosts and mosquito vectors responsible for viral maintenance. However, the virus exists as a single serotype and all vaccines are made from genotype III strains, with no evidence that they fail to prevent disease caused by viruses in other genotypes.

Strains isolated from nature exhibit a range of virulence in mice. With repeated cell culture passage, biologically derived neuroattenuated strains have been produced for use as vaccines.[94] As with other flaviviruses, important biologic functions, including attenuation and viral neutralization, are associated with the E glycoprotein. Combinations of mutations in genes of the E protein, nonstructural proteins, and noncoding regions have been associated with attenuation of the live vaccine strain SA 14-14-2 and so have been selectively incorporated with others into a chimeric JE vaccine using nonstructural proteins from the itself attenuated yellow fever 17D vaccine strain.[29]

JE virus is transmitted between birds, especially egrets and herons, and *Culex* mosquitoes; however, pigs, when present, are the most important source of viral amplification (Fig. 175E-1).[3,5,79,80] Pigs maintain high sustained viremias and may be hosts to thousands of mosquitoes in a single night, thereby serving as prolific sources of infected vectors capable of transmitting the virus onward. In rural Asia, the onset of human cases each summer occurs shortly after pigs become infected, following which the epidemic curves of human and pig infections evolve in parallel.[70] However, outbreaks of JE have occurred in areas devoid of pigs, where birds, including

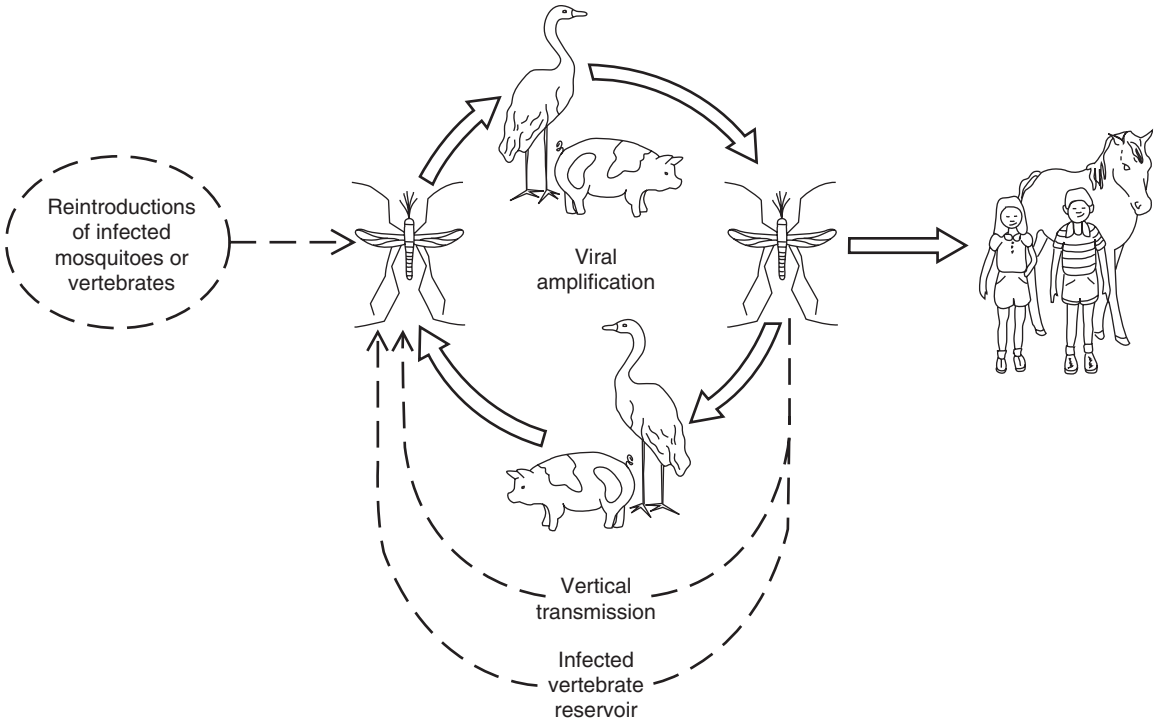

FIGURE 175E-1 ■ Transmission cycle of Japanese encephalitis virus. Speculative portions of the cycle are shown in *broken lines.*

ducklings, pigeons, sparrows, and possibly other small birds found near human residences, have served as amplifying hosts; furthermore, transmission in other sylvatic cycles is possible.[3,5,25,79]

C. tritaeniorhynchus is the major mosquito vector in most areas of Asia, and ecologic modeling of its predicted distribution in niches below 1000 m elevation (valleys in Tibet and Kathmandu are conspicuous exceptions), along with other environmental and climatic features, corresponds well to the distribution of human cases.[60,80] That distribution also overlaps the land cover used for rice paddies. *C. tritaeniorhynchus* exploit ground pools and especially rice paddies in their preadult stages, emerging in immense numbers from the flooded rice paddies responsible for 80 percent of the land cover in some areas and that frequently surround individual residences and villages. The vector is zoophilic and prefers to feed on large animals such as pigs and less so on humans, but with the custom of keeping pigs near or inside houses in rural Asia, residents live in the midst of the viral transmission cycle and are at high risk to be exposed to infected mosquitoes, starting at an early age. Living in proximity to a rice field and pig ownership understandably are risk factors for acquiring the illness.[55] Although *C. tritaeniorhychnus* is most active in the evening and night, because adults feed outdoors, bed nets are not entirely protective.

In various regions, other species *(Culex pseudovishnui*, *Culex vishnui*, *Culex gelidus*, *Culex fuscocephalus*, and *Culex bitaeniorhynchus)* with different habitats also may serve as vectors.[3,80] *Culex annulirostris* is the principal vector in northern Australia and the Pacific, and anopheline mosquitoes may contribute to transmission in northeastern India. The viral overwintering mechanism for JE virus has been a matter of speculation; however, vertical infection of mosquito eggs has been demonstrated as a means by which transmission is reestablished.[23,80] Viral persistence in local mammalian reservoirs such as bats, and reintroduction from external sources by migrating birds or windblown mosquitoes also may contribute to annual outbreaks and, the latter, to geographical spread of the virus.[5]

Domestic animals such as dogs and cattle can be infected, but their viremias are insufficient to support further transmission. Because they are attractive hosts to JE vectors, they may divert mosquitoes from humans, thereby protecting them from infection (zooprophylaxis). Horses can develop encephalitis, and outbreaks and economically significant loss of prize horses have led to routine use of equine vaccines in China, Mongolia, and Japan. Sows also are vaccinated, not to prevent illness in the animals, which remain asymptomatic after infection, but to prevent congenital infection of piglets, which may die in utero or may be born with lethal neurologic malformations.

Ecologic factors have been modeled to describe the seasonality of infection and to predict the occurrence and severity of outbreaks; surveillance tools include monitoring infections in pigs, birds, dogs, and horses, as well as precipitation and temperature. The potential impact of global climate on JE seasonality has been speculated, because warmer environmental temperature shortens the extrinsic incubation period of related flaviviruses, thereby speeding the transmission cycle. In support of this hypothesis, a secular trend toward an earlier onset of JE transmission in Taiwan has been noted, from June to

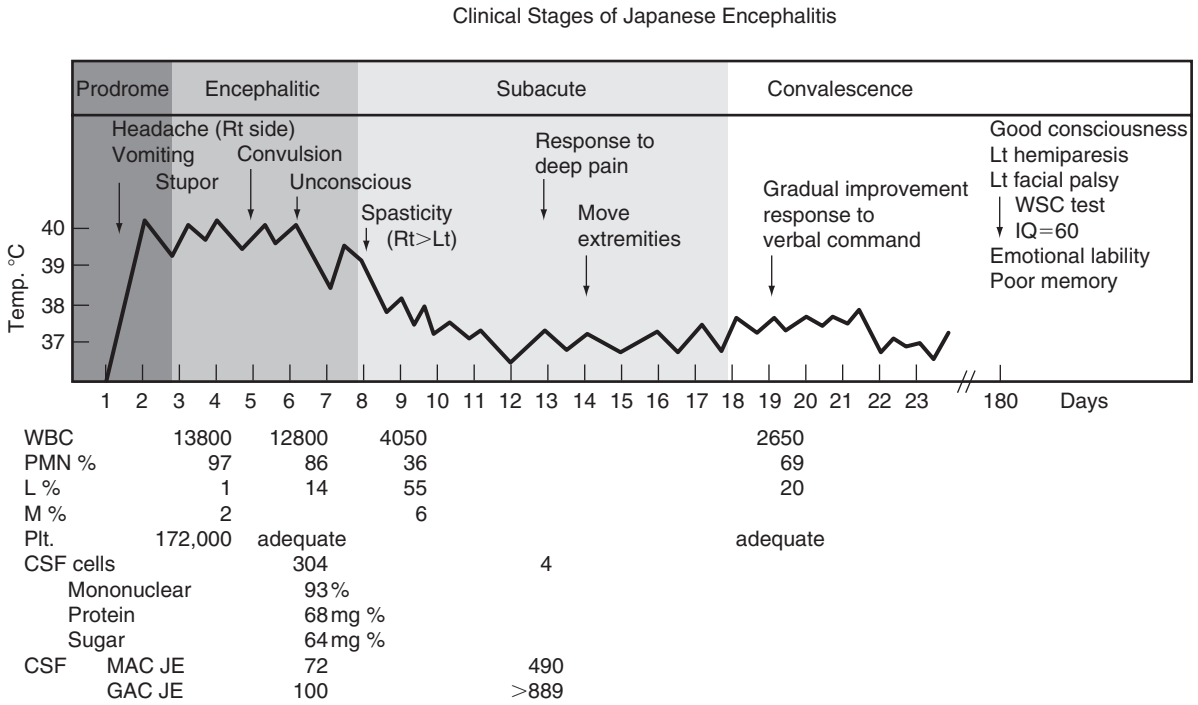

FIGURE 175E-2 ■ Clinical stages of a typical Japanese encephalitis case.

May, while high summertime temperatures have been associated with the occurrence and severity of West Nile and St. Louis encephalitis outbreaks.

EPIDEMIOLOGY

The disease occurs mainly in rural locations, where high levels of virus transmission lead to infection at an early age. In areas where children are not routinely vaccinated, cases occur mainly in children after the first year of life, with a slight preponderance in boys. More than 99 percent of infections are subclinical, and cumulative exposure with age leads to seroprevalence rates of 80 percent or more by adulthood.[27] In Japan and other developed Asian countries, where children are protected by routine vaccination, adult cases now predominate.[2,43,48] A majority of cases occur in adults over 45 years of age, because of immunosenescence and age-related chronic diseases that may be risk factors.

Transmission is seasonal, during late summer and early fall in temperate regions (July to October) and over a longer interval in southern China and Southeast Asia (April to November).[95] Transmission patterns are more complex in tropical areas, where mosquitoes proliferate after monsoon rains, and multiple epidemic seasons or year-round transmission is possible in some tropical locations. Although mosquito abundance usually corresponds to the rainy season, in many locations, vector populations now follow irrigation-controlled schedules of rice field flooding and other patterns dictated by mechanized rice production.[67]

JE transmission is endemic in nearly every country in Asia (Fig. 175E-2), with an estimated 60,000 cases reported annually from the region.[10] Annual incidence rates range widely from less than 0.01 to 5/100,000, depending on vaccine coverage and environmental conditions, and epidemic attack rates as high as 100/100,000 have been described. Incidence is underestimated because the unavailability of laboratory confirmation limits specific diagnosis and surveillance. Rare outbreaks have occurred in Oceania, on Guam and Saipan in 1949 and 1989, respectively, and in far northern Australia in 1995 and 1998.[31,69] These self-limited outbreaks occurred after the virus was introduced by migrating birds or other mechanisms, coupled with unusual conditions of human activity or weather patterns, but transmission was not sustained after the exhaustion of susceptible hosts. Establishment of JE virus on the Australian mainland appears to have been limited by the zooprophylaxis provided by dead-end hosts, as well as an immune barrier resulting from infections with other flaviviruses.[90] Few cases are reported from countries where vaccination rates are high (e.g., Japan, Korea, and Taiwan) and where development through urbanization, decreased land under cultivation, and improved standards of living have reduced human exposure. The use of agricultural pesticides and centralized pig rearing also may have contributed to lowering risk. However, the small number of human cases belies the persistence of enzootic viral transmission; for example, in Japan, more than 80 percent of pigs and 2.6 percent of the human population still are infected each year.[2,44]

Although economic development has paralleled a decline in JE, in some areas, development in the form of deforestation, construction of dams, and irrigation schemes has led to increases in transmission of JE virus or its emergence in areas where the disease had not occurred previously. Examples include development

projects in the Terai in southern Nepal and the Mahaweli Valley in Sri Lanka, where JE and malaria have become hyperendemic after large-scale programs of deforestation and agricultural development.

Travelers to areas where JE is endemic may be at risk for acquiring the illness.[33] Updated information may be obtained from the Centers for Disease Control and Prevention (CDC) at the website http://www.cdc.gov/travel/. Approximately 80 cases have been reported in travelers and expatriates (including military personnel and their family members) from North America, Europe, Russia, and Australia in the past 20 years, but the number undoubtedly is larger because of underreporting. The risk for acquiring the disease can best be described as serendipitous—cases have been reported in travelers who were infected within days of arriving in Asia, who never visited a rural area, and who had none of the risk issues cited in recommendations. The generally low but difficult-to-predict risk can be understood by factoring the probability of development of an illness after a single mosquito bite—only certain vector species transmit the virus, typically less than 3 percent of vector mosquitoes are infected, and only one in several hundred infections leads to clinical illness. Other factors entering into the risk for acquiring infection and illness are described in Table 175E-1)

CLINICAL MANIFESTATIONS

Because the overwhelming majority of infections are inapparent or manifested as mild self-limited illnesses, occasional cases of JE viremia are identified in serologic studies of children with undifferentiated fever, which might otherwise have been diagnosed clinically as dengue or another viral syndrome. However, patients who develop neurologic infection usually are profoundly ill and 5 to 25 percent of cases are fatal. After an incubation period of 4 to 14 days, the illness begins with lethargy, nausea or abdominal pain and vomiting, headache, and feverishness (Fig. 175E-3).[4,45,46,52,78] The prodrome is followed over several days by increasing lethargy or uncharacteristic patterns of behavior and motor disturbances, leading eventually to deep depression of consciousness and coma. The initial presentation varies, however; in some cases, it may be a sudden seizure, whereas in others, there may be a long prodrome of a week or more, with periods of confusion or agitation and unsteadiness of gait and other motor abnormalities. Unusual manifestations, such as acute psychosis and Guillain-Barré syndrome, also have been reported; the latter enter into the diagnosis of acute flaccid paralysis in areas of Asia where acute flaccid paralysis surveillance for polio still is maintained.[77]

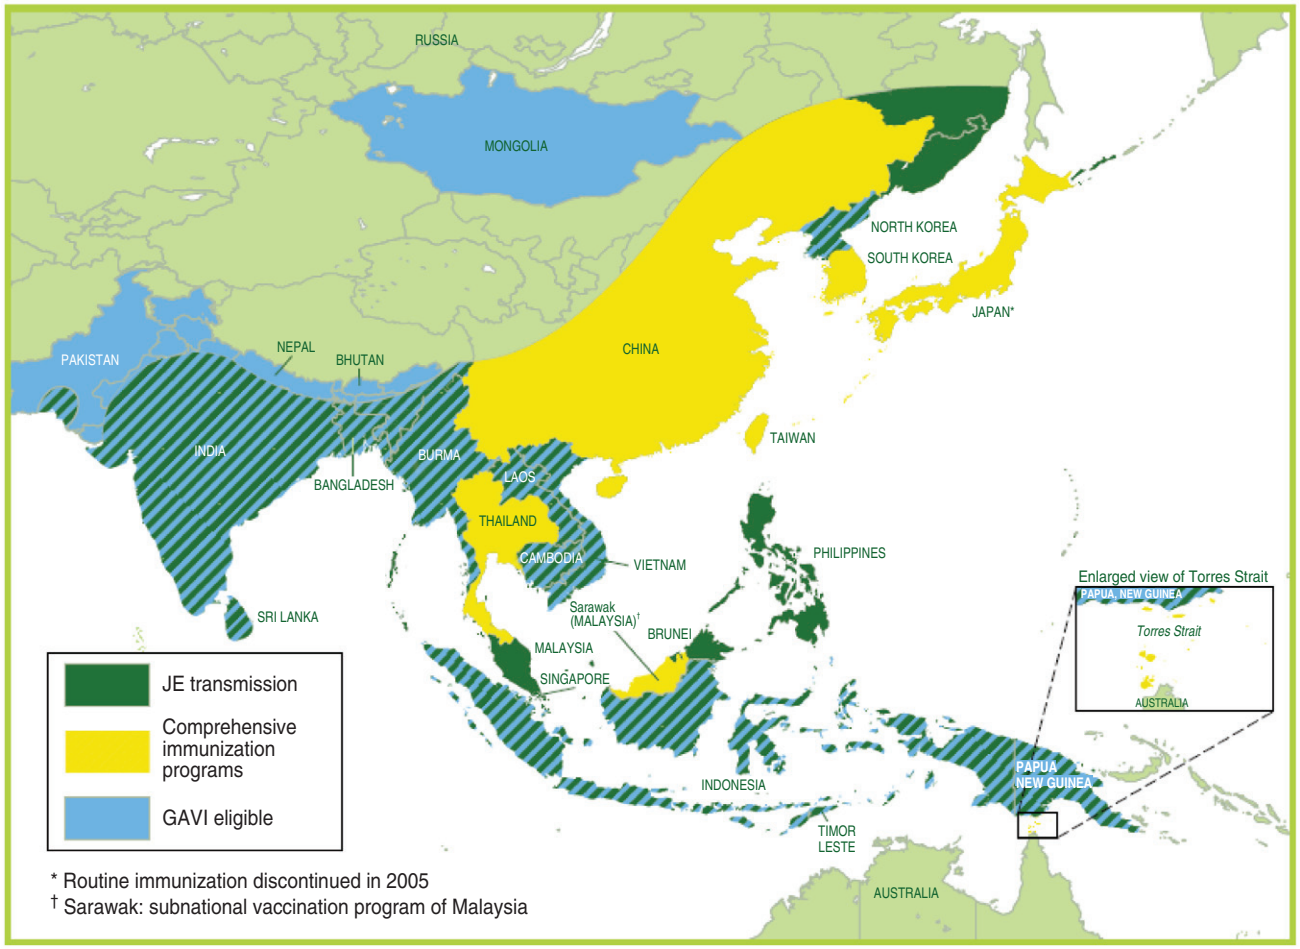

FIGURE 175E-3 ■ Locations where Japanese encephalitis is prevalent. (See companion Expert Consult website for color version.)

TABLE 175E-1 **Factors to Consider in Recommending Japanese Encephalitis Vaccine for Travelers to Asia**

Factor	Comment
Expatriates	During extended assignments, expatriates likely will make unanticipated trips within the region, including to areas where the risk for acquiring Japanese encephalitis (JE) is high or unknown. In many countries, local companions will have been vaccinated and/or will have naturally acquired immunity; an expatriate child could be alone in being unprotected among the local population if unvaccinated.
Visiting friends or relatives	Returning families may be more likely to visit ancestral villages or other locations that pose a greater risk for viral transmission. Parents may have been vaccinated or have acquired natural infections before they emigrated and may not realize that their own children are unprotected.
Travelers with open itineraries	Wanderjahr and other travelers who have open itineraries may journey to locations where risk for disease is higher, including rural areas.
Frequent travelers	Travelers who have second homes in the region or who travel frequently to Asia, even if individual trips are brief, have a cumulative risk for exposure that may justify vaccination, particularly because seroprotective antibodies may persist for years after one booster immunization.
Season	Only generalizations can be made about the seasonality of transmission within the region. In East Asia, which has a temperate or subtropical climate, transmission usually is described as extending from April to October, but within individual countries even the size of Thailand, transmission periods may differ by several months from north to south, or, as in China, from West to East. In the tropical zone, the virus may be transmitted year-round with superimposed patterns of higher risk. In many locations, seasonal monsoons dictate the periods when mosquito vectors are prevalent and those patterns can differ within surprisingly delimited geographic bounds, such as for Southeastern versus Southwestern India. Historical seasonal patterns may not be predictive in any given year. As rice cultivation has become more industrialized, the timing of rice field flooding and resulting blooms of vector mosquitoes may not correspond only to natural patterns of rainfall.
Activity out of doors	Persons with occupational exposure outdoors or whose activities during travel take them outdoors, especially at twilight and evening, are more likely to be exposed to the principal JE mosquito vectors, which are mainly exophilic (prefer to bite outdoors) and crepuscular (most active at twilight and evening). In contrast, the principal dengue vector, *Aedes aegypti*, is frequently encountered indoors and is active during the day. Even brief episodes outdoors (e.g., an elephant ride, have been reported in case histories of travel-associated JE).
Exposure to vector mosquito habitat	Most recommendations cite "rural exposure" as a risk factor for acquiring JE. However, "rural" is used in this context as a proxy for exposure to rice paddies that are highly productive habitats for JE vectors. Rice paddies, however, are found at the edges or even within major Asian cities (e.g., in Denpasar, Indonesia, the city greenbelts are rice fields). Moreover, other pools of water (e.g., flooded ditches) can support species capable of transmitting JE virus; thus infected mosquitoes and seroconverting sentinel animals have been detected in urban or suburban surveillance sites. Sporadic cases in local residents and cases in travelers have occurred in persons who stayed exclusively in cities. A 2.6% incidence of natural infection is estimated in the population of Japan, an industrialized country with shrinking agricultural lands.
Exposure to pigs	Because pigs are highly important in amplifying JE virus in the usual transmission cycle, locations with few or no pigs may pose a lower risk for encountering viral-infected mosquitoes. However, windblown mosquitoes can travel miles in a single evening. In addition, birds, ducks, and potentially other vertebrates, also can amplify the virus and have been implicated in outbreaks.
Age	Infants and older adults are at an increased risk for developing neurologic disease after infection in contrast to young adults. This epidemiologic pattern of age-specific risk is seen in nearly every other flaviviral infection that causes encephalitis, including St. Louis encephalitis, West Nile encephalitis, tick-borne encephalitis, and Rocio encephalitis.
Chronic disease	Immunocompromising conditions, including HIV infection, increase risk for illness. Thymus disorders and thymectomy have been associated with increased risk for vaccine-associated disease following yellow fever (another flavivirus) vaccination. Other chronic diseases, including cardiovascular disease, hypertension, and metabolic conditions have been associated with risk for illness or increased severity of illness for other flaviviruses. As observational and experimental data indicate that certain underlying neurologic diseases (e.g., neurocysticercosis and other concurrent neurologic infections) can facilitate neuroinvasion, it seems possible that CSF shunts, cochlear implants, baclofen pumps, and other implanted devices as well as other neurologic disorders could pose a similar risk.
Pregnancy	JE acquired in pregnancy has been associated with miscarriage and fetal death. Data are insufficient to assess risk by stage of pregnancy. No safety or immunogenicity data are available for use of the only available JE vaccine in the United States, an inactivated cell culture–derived vaccine, in pregnant women (Pregnancy category C).

Continued on following page

TABLE 175-E1 **Factors to Consider in Recommending Japanese Encephalitis Vaccine for Travelers to Asia** (Continued)

Factor	Comment
Genetic factors	Several studies suggest that persons homozygous for *CCR5*Δ32 are at increased risk for clinical illness from the flaviviruses, West Nile virus and tick-borne encephalitis virus. This deletion is so uncommon in Asia that it is unlikely to be unimportant as a risk factor among the indigenous population; however, it is a consideration for persons with other ancestries.
Concurrent medication	Because maraviroc is an inhibitor for CCR5, treated patients hypothetically may be at increased risk for developing JE or for more severe illness.
Previous flaviviral infection or vaccination	No protection has been confirmed from either yellow fever or tick-borne encephalitis vaccination. The contribution of previous dengue infection in modifying risk for JE is unclear, despite the presence of cross-reactive antibodies that can be demonstrated in dengue patients.
Vaccine safety	The only available JE vaccine in the United States, an inactivated Vero cell–derived vaccine, is well-tolerated and has not been associated with any safety issues since its licensure in the United States, Europe, and Australia in 2009. Studies of the vaccine that included a hepatitis A vaccine comparator indicate a similar level of acute safety.
Vaccine cost	As a rule, travel vaccines are not reimbursed by health insurance schemes, so the decision to take the JE vaccine is a decision for an out-of-pocket discretionary "purchase." Therefore, highly personal factors, which should be explored and respected, may enter into that decision. Individual judgments on events with great impact or that are potentially catastrophic, such as JE, may be assessed by certain individuals as more important to prevent than more mundane but more likely risks.

The principal physical findings are high fever and alterations in consciousness, ranging from mild mental clouding, frank disorientation and delirium, to coma. Some children exhibit bizarre behavior, including mutism, shouting, spitting, and personality changes. Signs of meningeal irritation are present. Cranial nerve palsies, mainly disconjugate gaze and central facial paralysis, are observed in a third of cases, and generalized or focal motor weakness can usually be demonstrated, presenting with either flaccid or spastic paralysis. Some patients exhibit erratic flailing movements, tremor, rigidity, expressionless facies, or thick slurred speech; frequently, choreoathetosis and other extrapyramidal signs become evident only in the second week of illness. Focal or generalized seizures develop in 50 to 75 percent of patients. Papilledema is seen in 10 percent of cases, along with hypertension, indicating increased intracranial pressure. In more than a third of patients, coma and respiratory failure necessitate ventilatory support. Patients with fulminant infections may die within the first 5 days of illness.

Recovery is slow, with defervescence of fever followed by gradual improvement of neurologic function over several weeks. Convalescence frequently is complicated by stasis ulcers, urinary tract infections, pneumonia, and bacteremia that may be secondary causes of death. In anecdotal cases, a biphasic pattern of illness has been described, with a recurrence of motor and behavioral abnormalities 2 to 5 weeks after initial improvement, accompanied by larger and more numerous associated lesions on magnetic resonance imaging (MRI). Recovery of motor function and adaptation to sequelae may progress over a period of months to years, although in some cases, residual neurologic abnormalities may not declare themselves until after hospital discharge.

Routine laboratory studies initially show a peripheral leukocytosis, often with a left shift and a total leukocyte count as high as 30,000/mm^3. Opening pressures on lumbar puncture usually are normal or slightly elevated. Cerebrospinal fluid (CSF) pleocytosis ranges from fewer than 10 cells to several thousand, with a median of several hundred per cubic millimeter, potentially leading to a misdiagnosis of bacterial meningitis. Lymphocytic pleocytosis follows, and CSF glucose and protein levels frequently are normal (80% of cases); when elevated, protein levels rarely exceed 100 mg/dL.

Electroencephalograms typically show diffuse theta to delta wave slowing, whereas spike and seizure discharges are relatively uncommon. MRI is more sensitive using T2-weighted and fluid attenuation inversion recovery (FLAIR) sequences in early stages of illness, with a relatively lower sensitivity from diffusion-weighted signals.[30,59] A distinct pattern of hyperintensity in the thalamus, basal ganglia, and brain stem has been noted, although cortical, cerebellar, and spinal cord involvement also are seen. JE-associated abnormalities have been reported to appear more frequently in the ipsilateral hemisphere affected by neurocysticercosis-related changes. Electromyograms show a neurogenic pattern consistent with anterior horn cell involvement.[86] Central motor conduction times are prolonged, indicative of diffuse subcortical damage.

PATHOLOGY

Although JE presents clinically as a central nervous system (CNS) infection, often overlooked is that the infection is pantropic, with pathologic changes found in the lungs and viscera, in addition to the brain.* On gross examination, the brain appears swollen and the meninges

*References 20, 35, 38, 50, 84, 96.

may be congested with macroscopically visible punctate hemorrhages. Microscopic examination discloses a moderate inflammatory response in the meninges. The parenchyma shows foci of neuronal degeneration and parenchymal and perivascular inflammatory responses principally in the thalamus and brain stem, but also more widely, in the hippocampus, temporal cortex, cerebellum, and spinal cord. Areas of neuronophagia may be surrounded by microglial nodules, but sharply defined round areas of softening or necrolysis without an inflammatory response also are seen. Purkinje cells and cerebellar glial shrubs also may be lost.[96]

PATHOPHYSIOLOGY

After virus is introduced by a mosquito bite, replication locally and within regional lymphatic tissue leads to a secondary amplified viremia and disseminated infection that includes the CNS. Neuroinvasion is thought to occur through cerebral capillaries as virions cross from the vascular side of the endothelial cell to the perivascular space, with subsequent neuronal infection, or by infected inflammatory cells crossing the brain barrier. Neurons show evidence of viral antigen in the cell body, axons, and dendrites, indicating cell-to-cell viral spread within the brain.[19,40,49] CSF levels of catecholamines and their metabolites are acutely lowered.[41] Infiltrating T cells elicit a broad inflammatory response, with B cells, T cells, and macrophages found in perivascular cuffs and macrophages and T cells in the parenchyma.[40,92] Neuronophagia proceeds with the formation of microglial nodules and the eventual disappearance of neurons, leaving ghostlike remnants with antigen accumulated within macrophages.

Relatively low levels of circulating neutralizing antibodies, approximately 1:10, correlate with protection and the rapidity of the neutralizing antibody response in naïve individuals is a principal determinant of outcome.[8,9,40,64] Most fatal cases occurring within approximately 5 days after the onset of illness have no detectable CSF antibody response while virus is recoverable from the CSF, indicating unimpeded viral replication.[8,9] In experimentally infected animals, passive immunization reduces mortality, even when it is given 4 to 5 days after inoculation.[64] However, the persistence of viral antigen in neurons for extended periods in the presence of intrathecal antibody and immune complexes in some cases, and development of antineurofilament antibodies, indicate the importance of viral clearance and potential for immunopathology in delayed or incomplete resolution of illness.[19,20] The role of innate immune responses is not well characterized, but they may contribute toward both control of infection and immunopathology.[89,92] The contribution of interferon and CCR5 ligands in susceptibility may be inferred from studies of other flaviviral infections that associated risk with oligoadenylate synthetase polymorphisms and *CCR5*Δ32 gene deletions.[8,51] Elevated CXCL8 levels in serum and CSF have been associated with increased disease severity and duration.

Why most JE virus infections are subclinical or lead to no signs of infection in the CNS is unclear. Epidemiologic observations indicate an elevated risk for JE in the elderly and increased severity in young children, but the biologic basis for age-related susceptibility remains poorly understood. Tumor necrosis factor–α promoter polymorphism also has been suggested as a specific risk factor.[74] Pathologic observations have shown a higher prevalence of neurocysticercosis in fatal JE cases than in deaths from other causes, which suggests that physical or physiologic disruption of the brain architecture by infection or other mechanisms could facilitate neuroinvasion (see earlier discussion).[18,54,86] Experimental dual infection of animals with JE virus and other agents supports this hypothesis. In experimental animals, other host factors associated with a risk for acquiring illness and poor outcome include flavivirus-specific susceptibility genes, age, levels of sex hormones, and cold and stress responses. Because dengue infections are prevalent across much of the JE-endemic region, the role of cross-reactive flaviviral immunity in the clinical outcome of JE is of considerable interest; unfortunately, no clear pattern of protection or increased risk has been confirmed.[1,24]

COMPLICATIONS

The principal risk is secondary bacterial infection occurring in the acute and subacute phases of illness. In addition, concurrent malaria and other parasitic or bacterial infections that are endemic in Asia may complicate management. Although JE occurs in areas of Asia where human immunodeficiency virus (HIV) infection is prevalent, data are insufficient to conclude differences in outcome in coinfected patients. Stress-induced gastrointestinal hemorrhage and hyponatremia caused by inappropriate antidiuretic hormone secretion also can complicate treatment.

Interestingly, cases of clinical relapse with seizures, coma, and weakness, several occurring 6 to 9 months after recovery from the acute illness, have been reported.[73,76] These and other patients experiencing relapse had evidence of persistent JE virus infection in peripheral blood mononuclear cells.[85] A study of 253 patients found laboratory evidence of subacute CNS infection in 5 percent of cases, with persistent intrathecal production of JE virus–specific immunoglobulin (Ig)M beyond 50 to 180 days or CSF containing JE virus antigen or virus more than 3 weeks after recovery.[76] These observations suggest that some infections may be followed by viral persistence but additional confirmatory studies are needed.

JE acquired during the first two trimesters of pregnancy may lead to fetal infection and miscarriage, which has been confirmed by viral isolation from products of conception in a few cases.[13,57] Infections acquired during the third trimester, however, have not been associated with adverse outcomes to the pregnancy. It is still unknown whether sublethal malformations can result from congenital infection and whether subclinical infections acquired during pregnancy pose a risk for fetal infection. Because JE virus is a proved teratogen in pigs, producing fetal death and CNS malformations, there is a need for closer studies in humans.

LABORATORY DIAGNOSIS

A specific diagnosis can be made serologically by identifying JE virus–specific IgM antibody in serum or CSF by enzyme-linked immunosorbent assay (ELISA); often, however, results need to be confirmed by demonstrating fourfold titer changes in neutralizing antibodies between acute-phase and convalescent-phase serum samples to resolve cross reactions to dengue and other flaviviruses. Several IgM detection kits exhibiting good sensitivity and specificity are commercially available.[61,75] IgM can be detected in serum or CSF (or in both) in nearly all cases by 1 week after the onset of illness. Detection of NS1 in CSF also has been reported to augment the sensitivity of serologic diagnosis. Although real-time polymerase chain reaction (PCR) and reverse transcription–loop-mediated isothermal amplification (RT-LAMP) assays have been described, their limited availability in the endemic situation has limited opportunities for evaluation. Available reports indicate that as a result of the sensitivity of these methods, both acute serum samples and CSF should be tested, because viremia may be detected early in infection in the preneuroinvasive phase of illness, although usually no later than 6 to 7 days after onset. Viral infection frequently is cleared by the time lumbar punctures are performed; therefore CSF should be tested both for IgM and by PCR to maximize the chances of making a specific diagnosis.

Virus can be recovered from brain biopsy and autopsy material by intracerebral inoculation of baby mice and various cell cultures, such as primary chick or duck embryo cells, and in Vero, LLCMK-2, C6-36, and AP-61 cell lines.

DIFFERENTIAL DIAGNOSIS

Other mosquito-borne arboviruses that also cause encephalitis—West Nile, Banna, and Chandipura viruses—and that, in some circumstances, are transmitted by the vectors that also spread JE virus, are frequently mixed among JE cases in seasonal endemic and even epidemic settings.[28] As specific diagnostic assays are even less accessible for these infections than for JE virus itself, they may be responsible for some of the overall burden of seasonal encephalitis syndrome cases currently attributed to JE. Infections caused by West Nile, and also, dengue virus, which frequently produces encephalopathy, are particularly difficult to differentiate by routine serologic methods because of the antigenic relatedness of the viruses. JE has been misdiagnosed as tubercular or pyogenic meningitis, but more often cannot be differentiated clinically from other causes of viral encephalitis.[47,66] Enterovirus 71, Nipah virus, and hepatitis E virus—the latter two associated with pig contact—are transmitted in Asia in epidemiologic contexts similar to those of JE and can present with CNS signs and symptoms. Other infections that may enter the differential diagnosis include typhoid fever, which can present with tremor and lethargy similar to the prodrome of JE, and scrub typhus, which rarely can present with meningitis, although rash, adenopathy, and an eschar, if present, are helpful diagnostic signs. Acute encephalitis with seizures is encountered in two thirds of patients with neurocysticercosis, a prevalent chronic condition in some areas of Asia that may increase the risk for acquiring JE (see the discussion on pathophysiology). Where poliomyelitis still has not been confirmed to be eradicated, JE should be included among the possible causes of acute flaccid paralysis.

Noninfectious causes of acute encephalopathy to be considered include heat stroke, autoimmune encephalitis, vascular occlusion and intracranial hemorrhage, acute electrolyte disturbances, Reye syndrome, lead encephalopathy and other poisonings (including insect repellent toxicity), and inherited metabolic disorders.

TREATMENT

No specific antiviral therapy is available. A few patients have been treated with interferon-α, but its efficacy has not been evaluated in wider trials.[32] Supportive care and control of increased intracranial pressure are critical for a good outcome. Mannitol or hypertonic saline is used routinely to control raised intracranial pressure, and early high-dose dexamethasone therapy was shown to have no clinical efficacy in a prospective controlled clinical trial.[36] Corticosteroids also have been given, without apparent benefit, in the late stages of illness as empirical therapy for late neurologic changes that were presumed to have an immunopathologic basis. Other supportive measures, including control of fever and seizures, attention to fluid balance, respiratory support, and prevention and treatment of secondary infections, have contributed to increased survival and improved outcomes. Small interfering and hairpin RNA molecules, and minocycline, administered as an immunomodulator, are being investigated as therapeutic agents.

PROGNOSIS

The case-fatality ratio varies from 5 to 35 percent, depending on the accessibility and quality of supportive care. Younger children (<10 years of age) are more likely to die of the infection and to have more serious neurologic complications acutely and as sequelae. Gross neurologic impairment, such as paralysis, weakness, abnormal muscle tone, seizures, ataxia, and extrapyramidal movement disorders, are found in approximately a third to half of recovered patients several months to a year after onset.[34,56,62,82] Electroencephalographic abnormalities have been detected in more than 50 percent of surviving children 1 year after recovery. The graver clinical consequences of JE in contrast to other forms of encephalitis necessitating hospitalization were clearly shown in a follow-up study 6 to 27 years after hospitalization that disclosed neurologic deficits on examination in 22 versus 2 percent of the subjects and subnormal intelligent quotients in 28 versus 2 percent, respectively.[23] Thus, in areas where the disease is prevalent, JE may account for

substantial disability in the resident population. Optic atrophy and chronic seizures have been reported to have a delayed onset of 3 to 17 years after hospital discharge, indicating the need for long-term follow-up.[23] On the other hand, another study suggested that compensatory improvements of acute deficits continue even after a decade.[81]

PREVENTION

JE vaccine is administered routinely under the World Health Organization's Expanded Programme on Immunization and national schedules in most Asian countries (Fig. 175E-3). Several JE vaccines are used, of which the most widely distributed is a live attenuated vaccine made from the SA14-14-2 strain, produced in China.[88,94] Efficacious inactivated mouse brain–derived vaccines largely have been discarded because of associated allergic and neurologic adverse events and are being displaced by Vero cell–derived inactivated vaccines, including in the United States and Europe.[71,72] Another live vaccine, derived as a chimera of the yellow fever 17D vaccine strain and the envelope protein of the SA14-14-2 virus, has been licensed in several countries but has not yet been distributed widely.[29] An inactivated vaccine grown in primary hamster kidney cells is used to a limited degree and only in China. Currently no JE vaccine is licensed for use in children in the United States. Pediatric clinical trials are ongoing, and information on these clinical trials may be obtained at the website http://www.clinicaltrials.gov. In addition, a list of clinics for international travelers that may be administering the JE vaccine to children is available at the CDC website http://www.cdc.gov/ncidod/dvbid/jencephalitis/children.htm.

An inactivated Vero cell–derived JE vaccine, made from the SA14-14-2 strain, is licensed in the United States for adults and internationally for use in travelers; others produced with different viral seeds are licensed in Asia for local use.[42] Two intramuscular doses of 6 μg separated by 28 days produced seroconversion to protective (>10) neutralizing antibody titers in 96 percent of adult subjects with few local and systemic reactions and was noninferior to three doses of the mouse brain–derived vaccine. Protective antibody titers were maintained in 48 to 82 percent of subjects at 24 months with geometric mean titer (GMT) of 16 to 44. When subjects were vaccinated 15 months after primary immunization, all responded to a booster dose with a GMT of 900 that remained elevated at a GMT of 361 at 1 year later.[12] A single booster dose in subjects who previously had been vaccinated with the inactivated mouse brain vaccine produced a response in more than 95 percent, indicating interchangeability of the two inactivated vaccines. Limited data in children indicate 100 percent seroconversion to a protective antibody titer after two 3 μg (children <3 years of age) or 6 μg doses (children 3 to 18 years of age), with GMTs of 216 to 332 and that persisted at titers of 48 to 84 at 6 months later. Reactogenicity was similar to that of the PCV7 control vaccine, and no safety signals have emerged in postmarketing surveillance.[83] Compatible coadministration of the vaccine with hepatitis A vaccine has been demonstrated in adult subjects.

More than 100 JE cases have been reported in travelers from Europe, including Russia; North America; Australia; and Asia; therefore, vaccination of certain travelers is recommended.[6] Current U.S. recommendations specify vaccination for expatriates, for travelers spending 30 days or more in an endemic area during the transmission season, and for persons with briefer itineraries if they have a high risk for exposure (see Table 175E-1).[11,33] The course of immunization should be completed 7 to 10 days before the onset of travel. These recommendations are highly conservative, however, because cases in travelers have been reported in individuals with briefer itineraries and without the cited risk factors, and who later died or survived with serious neurologic damage. The narrow criteria defined in the recommendation are a legacy of committee efforts to limit use of the highly reactogenic mouse brain–derived vaccine, which was the only licensed vaccine when recommendations initially were formulated.[11] With the availability of a safer inactivated vaccine, the changed risk-benefit of vaccination has prompted reconsideration of these recommendations.[6,7,58,91] Because the illness has such a high clinical impact and the risk for acquiring the infection is serendipitous—although low—thoughtful counseling is needed while discussing the risks for the disease, vaccine cost, and other factors, so that travelers can make an informed decision (see Table 175E-1).

The live attenuated SA 14-14-2 vaccine is used in areas of China, India, Nepal, Sri Lanka, North Korea, Thailand, and Cambodia. Although the recommended schedule of immunization is three doses given at 1, 2, and 6 years of age, case-control effectiveness studies suggest that two doses could be 98 percent effective. Some case-control studies suggest that one dose could be effective; however, primary vaccine failure was shown in 5 percent of 9- to 15-month-old children who failed to respond serologically to the first dose of vaccine.[17,65] Although the strain is highly attenuated, with low reactogenicity, safety studies are limited. A report of four JE cases occurring in temporal relationship to vaccination could not distinguish vaccine failure from vaccine-associated encephalitis, indicating a need for additional safety surveillance.[39] No data are available on its use in HIV-infected or other immunocompromised patients. Coadministration with measles vaccine showed measles antibody titers were lowered, but not significantly so.

The live chimeric vaccine led to seroconversion to a GMT of 230 in 97 percent of adults 6 months after a single dose, with 93 percent retaining protective antibody levels at a GMT of 70 at 5 years.[87] Antibody persistence was modeled to show that 90 percent of subjects would remain seroprotected at 8 years.[21] Well-tolerated, compatible or sequential administration with yellow fever 17D vaccine was shown.[63] In 12- to 19-month-old toddlers, 92 to 95 percent seroconverted, with persistence of antibodies to a GMT of approximately 80 in 84 to 90 percent after 2 years.[16,26] A low level of viremia was detected in 5 percent of vaccinated children on the fourth day after vaccination; the vaccine was as well tolerated as

the comparator hepatitis A vaccine. Cautions associated with the use of the live vaccine in immunocompromised persons, at the extremes of age, and in other populations have not been specifically defined.

Although vaccination is recommended to prevent infection and illness, avoidance of outdoor activities during the evening hours, staying in screened or air-conditioned quarters, and sleeping under a bed net also will lower the risk for acquiring the illness by reducing exposures to vector mosquitoes. Wearing long-sleeved shirts and long pants and using mosquito repellents on clothing and exposed skin are recommended for outdoor activities.

From a public health perspective, routine childhood vaccination with the live SA14-14-2 vaccine has been shown to be highly cost-effective.[53,93] Pig vaccination is ineffective and impractical, although moving pigs sties and pig production facilities at a distance from the human population can reduce disease risk. Mosquito control is impractical, but agricultural practices, such as schedules of rice production and changes in water levels, and non-targeted effects of agricultural pesticides have had secondary effects in reducing the vector population and cannot be excluded to have reduced human infections.

175F ■ MURRAY VALLEY ENCEPHALITIS

John G. Aaskov

Outbreaks of an acute, severe, encephalitic illness, clinically similar to Japanese and St. Louis encephalitis, occurred in rural areas of southeastern Australia in 1917, 1918, 1922, 1925, 1951, and 1974[1,9,14-16] and in north and northwestern Australia in 1981, 1993, and 2000.[8,12,41] Approximately 420 cases were reported in these nine outbreaks.[41] They are thought to represent a single entity for which various names (Australian X disease, Murray Valley encephalitis, Australian encephalitis) have been used. Twenty-two cases were diagnosed in the 5 years between 2007 and 2011; three were fatal, and one of the fatalities occurred in a Canadian tourist on return from a holiday in northern Australia.

Case-fatality rates, as high as 70 percent in the early years,[9,11] declined to 20 percent in the 1974 outbreak and have remained at about this level since then.[5,10,12] However, significant residual neurologic disability occurs in as many as 50 percent of survivors.[10,12]

The presence of this disease in Papua New Guinea was confirmed in 1956.[20] The causative virus was transmitted to experimental animals as early as 1918,[6,11] although those strains could not be maintained. The definitive isolation and characterization of Murray Valley encephalitis virus in 1951[19] led to epidemiologic studies that suggested its survival in bird-mosquito cycles in northern Australia but not in the area of epidemic occurrence in southern Australia.[1]

Murray Valley encephalitis is caused by Murray Valley encephalitis virus. In an effort to dissociate a disease from a specific locality, the term *Australian encephalitis* was proposed by residents of Murray Valley for the disease caused by Murray Valley encephalitis virus. Some researchers subsequently have attempted to expand the term *Australian encephalitis* to include encephalitis caused by any Australian arbovirus. Because the term *Australian encephalitis* has no scientific validity and is ambiguous, it should not be used.

ETIOLOGIC AGENT

Murray Valley encephalitis virus was isolated post mortem from the brains of patients in 1951 and 1974 and shown to be related antigenically to Japanese encephalitis virus.[19,28]

A partial nucleotide sequence of Murray Valley encephalitis virus[13] confirmed the previous classification of this virus, on serologic grounds, as being a member of the Japanese encephalitis, St. Louis encephalitis, West Nile fever subgroup of flaviviruses.[37] Four genotypes of Murray Valley encephalitis have been identified, two exclusively from Papua New Guinea.[24,29] However, the most recent isolates from Papua New Guinea are indistinguishable from Australian strains in genotype 1.[23]

TRANSMISSION AND EPIDEMIOLOGY

The mosquito *Culex annulirostris* is thought to be the major vector of Murray Valley encephalitis virus,[16,17,31] although other mosquitoes, such as *Aedes normanensis*, *Aedes tremulus*, and *Culex quinquefasciatus*, also may play a significant role in transmission of the virus.[7]

Murray Valley encephalitis virus is thought to survive in cycles of infection between birds and mosquitoes in northern Australia and Papua New Guinea,[1] where regular infection of humans and other animals is indicated by seroconversion in the summer-autumn "wet" season[16] as well as by clinical disease.[7,41] Studies also suggest that the virus might survive, after vertical transmission, in desiccation-resistant eggs of *A. tremulus* mosquitoes.[7] Epidemics that occurred in more populous areas of southeastern Australia are thought to have followed the introduction of virus when abnormal spring rainfall allowed chains of bird-mosquito transmission to occur through northern Australia.[2] However, several studies also have suggested that interepidemic survival of virus occurs in southern Australia.[21]

Although disease occurs most commonly in children, clinical infection occurs in individuals of all ages.* Data are insufficient to determine whether the lower incidence of disease in adults is due to immunity acquired from previous subclinical infections.

The recent report of a clinical Murray Valley encephalitis virus infection in a horse, with pathologic changes in the brain and spinal cord similar to those seen in humans,[23] confirms a previous, unconfirmed report of possible clinical Murray Valley encephalitis infections in horses[22] and raises the possibility that both wild and domestic horses could play a role in the transmission and dissemination of this virus.

CLINICAL MANIFESTATIONS*

An initial period of nonspecific prodromal symptoms and signs, such as fever, headache, nausea, vomiting, muscle pain, and photophobia, is followed within 2 to 5 days by drowsiness, mental obtundation, confusion, disorientation, incongruous behavior, ataxia, speech disturbance, or convulsions, sometimes with a grand mal character. Neurologic signs were present in most patients on admission to the hospital, and additional signs appeared as the disease progressed. In some cases, the signs fluctuated from hour to hour. Bennett[5] recognized three groups of patients according to eventual clinical outcome:

1. Patients with mild disease commonly had disturbed mentation short of coma, incoherent or slurred speech, aphasia, speech perseveration, incontinence, neck stiffness, intention tremor, and limb hypertonicity but rarely required assistance for respiration. The neurologic changes stabilized in 5 to 10 days, and the patients' clinical conditions improved.
2. Patients with severe disease showed more profound central nervous system (CNS) involvement consisting of impairment of consciousness to coma, more marked signs of upper motor neuron involvement, and pharyngeal or respiratory paralysis requiring artificial respiration.
3. In fatal cases, patients had either spastic quadriplegia progressing to almost complete loss of nervous function or severe disease with superimposed infection.

There also may be a fourth group with even milder signs and symptoms than Bennett's group 1. These are patients with mild or no encephalitis whose principal features are fever and headache.[40]

PATHOLOGY

A period of viremia probably precedes infection of the CNS, during the 1- to 3-week incubation period,[1] but it has not been demonstrated. Pathologic changes in fatal cases were restricted to the CNS and included extensive perivascular cuffing (especially in the cortex), lymphocytic infiltration of the meninges, neuron degeneration and neuronophagia in the cerebellum and spinal cord, and thalamic necrosis. Evidence of repair, including calcification, was described in patients who died late in the course of the disease.[6,10,11,36,39] These pathologic changes do not distinguish Murray Valley encephalitis from other arthropod-borne encephalitides.

In rodents infected peripherally with Murray Valley encephalitis virus, the virus enters the CNS through the olfactory pathway after replicating in regional lymph nodes. From the olfactory lobe, it spreads through interconnected neural circuits to the cortex, hippocampus, thalamus, cerebellum, medulla oblongata, and spinal cord. Extensive neuronal necrosis was observed in the olfactory bulb and hippocampus. The severity of the subsequent encephalitis correlated with the magnitude of mononuclear and polymorphonuclear cell infiltrates. Infiltration of neutrophils was preceded by increased expression of tumor necrosis factor-α and the chemokine N51/KC in the CNS. Previous depletion of neutrophils or inhibition of inducible nitric oxide synthetase resulted in prolonged survival and decreased incidence of mortality in mice infected with Murray Valley encephalitis virus.[3,32] However, the pronounced mononuclear cell content of cerebrospinal fluid in some patients with Murray Valley encephalitis[10,19] contrasts with the picture in rodents.[32]

DIAGNOSIS

Clinical and epidemiologic features may suggest the diagnosis of Murray Valley encephalitis, especially during recognized epidemics, but individual cases may be difficult to distinguish from cases of encephalitis or encephalopathy of other cause (e.g., herpesvirus or Japanese encephalitis or Kunjin viruses).[5,34,42] A differential diagnosis of Murray Valley encephalitis may be assisted by observing signs attributable to spinal cord involvement and cranial nerve palsies, tremor, and frequency of seizures (seizures rarely develop in adults with Murray Valley encephalitis, whereas they may occur in up to 90% of children). Although computed tomographic scans in these patients may be normal and electroencephalograms may not show focal features,[10] magnetic resonance imaging reveals changes similar to those reported in the brains of patients with Japanese encephalitis[25]—thalamic edema, hypointensity on T1-weighted images, and hyperintensity on T2-weighted images.[18,26,27] Changes also were noted in the reticular formation, the substantia nigra, and the cervical spinal cord.[18] In the absence of serology, the magnetic resonance images might be regarded as diagnostic of an infection with herpes simplex virus rather than with Murray Valley encephalitis virus.[42] Magnetic resonance imaging may provide a presumptive diagnosis within a week of onset of symptoms.

Establishment of a specific diagnosis depends on serologic evidence of infection concurrent with disease. Detection of IgM antibody that reacts with Murray Valley encephalitis virus in enzyme-linked immunosorbent assays is the most useful indication of recent infection. Other flaviviruses, especially Kunjin virus, may cause encephalitis, subclinical infection, or minor illness during epidemics of Murray Valley encephalitis,[41] and

*References 5, 9, 10, 12, 27, 40.

interpretation of serologic cross-reactions between Kunjin and Murray Valley encephalitis viruses may require specific tests (e.g., neutralization) with several viruses.[16] Serologic tests for the laboratory diagnosis of Murray Valley encephalitis are not available commercially and so are performed only at larger regional laboratories. Isolation of virus has not been successful for antemortem diagnosis. However, some reports[18,33] document the detection of Murray Valley encephalitis viral RNA in serum or cerebrospinal fluid from patients by use of the reverse transcription–polymerase chain reaction (RT-PCR). Subsequent serology confirmed these RT-PCR data. In response to the need for rapid clinical intervention in this disease, a number of laboratories now employ "in-house" RT-PCR assays as part of routine diagnosis.[33,38]

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available. Administration of corticosteroids has been recommended during the acute phase of the illness to reduce brain edema. Artificial respiration has been lifesaving, and all patients should be transported to base hospitals with facilities for the management of patients with respiratory paralysis.[5] Most patients also require parenteral nutrition or nasogastric feeding.[10]

The early epidemics left some patients with neurologic and psychiatric sequelae, but the lower case-fatality rate in recent outbreaks, presumably because of use of modern intensive care techniques, has been associated with a high rate of residual disability.[10,12] Bennett[5] observed 18 patients up to 16 months after they experienced infection. Four of 11 patients with mild disease had emotional problems and mild degrees of impaired motor coordination and mental acuity. All 7 patients with severe disease had serious defects, including paraplegia or quadriplegia and mental disturbance.

This pattern of high residual disability has continued to the present.[10,12]

PREVENTION

Because of the irregularity of outbreaks and the large areas over which they occur, implementation of measures to prevent Murray Valley encephalitis is difficult. Several Australian states have established sentinel flocks of chickens to provide warning of transmission of Murray Valley encephalitis virus, but there is no evidence that this information serves other than to alert residents to the need to enhance their mosquito avoidance measures.

There is no vaccine against infection with Murray Valley encephalitis virus, but there may be value in assessing the capacity of the live attenuated Japanese encephalitis virus vaccine that was recently licensed in Australia[35] to provide cross-protection against infection with Murray Valley encephalitis virus.[29]

175G ■ TICK-BORNE ENCEPHALITIS

Andrea Duppenthaler • Christoph Aebi • Theodore F. Tsai

Tick-borne encephalitis (TBE) refers here to the neurotropic tick-transmitted flaviviral infection that occurs across the Eurasian land mass from the Far East to western Europe. The Far Eastern form of the disease frequently is called Russian spring-summer encephalitis (RSSE); in Europe, where the disease is distinctly milder and often biphasic, it is called tick-borne encephalitis, spring-summer meningoencephalitis, central European encephalitis, or, because sometimes it is transmitted by raw infected milk, biphasic milk fever.[26,35,70,107]

HISTORY

After an outbreak of encephalitis in the Far Eastern region of Russia in 1932, Zilber isolated the virus from viremic humans and from *Ixodes persulcatus* ticks. A milder form of the disease with a similar seasonality was described previously in Sweden and Austria, but its etiology was not defined until 1948, when the virus was isolated in the Czech Republic and Slovakia. Milk-borne transmission of TBE virus (TBEV) from infected livestock animals first was recognized in an outbreak in 1951 and 1952.

ETIOLOGIC AGENT

TBEV and the closely related viruses of RSSE and Powassan encephalitis are flaviviruses placed antigenically within a complex of tick-borne flaviviruses that also includes the agents of Kyasanur Forest disease, Omsk hemorrhagic fever, and an encephalomyelitis syndrome

in sheep variously called louping ill in the British Isles and Spanish, Greek, or Turkish sheep encephalomyelitis in their respective countries.[43] Molecular taxonomic studies based on nucleotide sequence differences in the E glycoprotein gene of the virus show the early divergence of a mammal-associated clade from seabird-associated agents. Viruses in the mammal-associated clade exhibit a continuous east-to-west cline consistent with an evolutionary origin of TBEV in the Far East and dispersion westward to Europe and the British Isles (Fig. 175G-1).[31,88]

ECOLOGY

The viruses of RSSE and TBE are transmitted principally by hard ticks in the *Ixodes ricinus* complex—*I. ricinus* in Europe and *I. persulcatus* in the Far East.[35,70,107] Other tick vectors include *Ixodes arboricola*, *Ixodes hexagonus*, *Haemaphysalis punctata*, *Haemaphysalis concinna*, *Dermacentor marginatus*, and *Dermacentor reticulatus*. Viral circulation is maintained by continuous horizontal infection between ticks and animals and through the winter by vertical transmission in vector ticks and by latent infection in hibernating animals. The viruses are transmitted transstadially from larval to nymphal to adult tick stages and also transovarially. All stages of the tick and both male and female ticks transmit infection to animals and humans. Ixodid ticks feed on three hosts, one for each of the stages, during the typical 3-year life cycle. Larval and nymphal ticks feed preferentially on birds and small mammals, such as wild mice, voles, and dormice; adult ticks feed on larger mammals, such as roe deer, hedgehogs, foxes, hares, badgers, deer, domestic livestock (i.e., pigs, goats, sheep, and cows), dogs, cats, and humans. RNA sequence heterogeneity of the 5′ noncoding region in different TBE virus isolates recovered from the same biotope suggest that virus populations consist of subtypes with specificities for individual vertebrate hosts.[13] Infections in animals, except occasionally in dogs, are asymptomatic, and the viremia is of brief duration. Therefore, a large population of susceptible vertebrate hosts is needed to maintain viral transmission. Human infections are incidental to the natural cycle of transmission. Birds and large mammals contribute to the spread of vector ticks and viral foci.[80]

Ticks in the *I. ricinus* complex require high soil and ambient humidity (>80% to 90% relative humidity) and moderate temperature, within the 8°C (46.4°F) isotherm. They typically are found in the transitional vegetation zone from the forest edge to fields or meadows or in areas where dense brush or ground vegetation provides a sheltered microenvironment. Vector ticks are absent from mountainous areas with an elevation above 1200 to 1500 m. Foci of TBE transmission are restricted geographically and ecologically to these biotopes and have tended to be highly stable over years. However, global warming has been speculated to underlie the changes, both expansion and contraction of transmission foci, in northern and central-southern Europe,

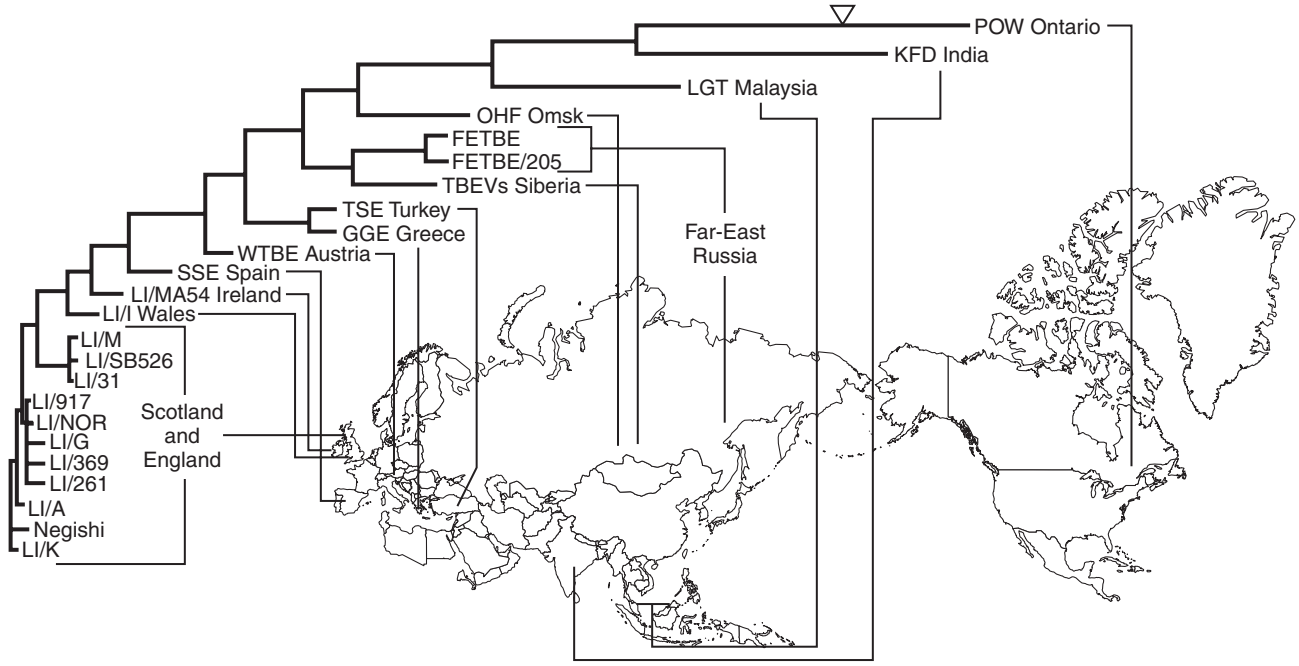

FIGURE 175G-1 ■ Cladogram of tick-borne encephalitis complex viruses based on E gene sequences presented from west to east with respect to louping ill *(LI)* virus. *FETBE,* Far Eastern tick-borne encephalitis; *GGE,* Greek goat encephalitis; *KFD,* Kyasanur Forest disease; *LGT,* Langat; *OHF,* Omsk hemorrhagic fever; *POW,* Powassan encephalitis; *SSE,* Spanish sheep encephalitis; *TSE,* Turkish sheep encephalitis; *WTBE,* Western tick-borne encephalitis. The phylogenetics of these and other mosquito-borne flaviviruses are rooted in the Powassan branch indicated by the triangle. (From Zanotto PM, Gao GF, Gritsun T, et al. An arbovirus cline across the Northern Hemisphere. Virology 1995;**210**:152-159.)

respectively.[79,107] New data also suggest a shift of tick activity to higher altitudes in recent years, potentially allowing vertical expansions of TBE foci.[21]

Tick activity varies with seasonal temperature and humidity. In central Europe, activity begins in March and April, reaches a peak in May, and declines during the summer in July and August. With the return of cooler temperatures, a second peak of activity occurs in September. In temperate regions, tick activity begins later and is greatest in the summer months. In Mediterranean climates, ticks are most active from November to January.

In foci with hyperendemic transmission, tick density may exceed 1/mm^2. Viral infection rates in ticks generally are in the range of 0.1 to 5 percent.[14] These rates typically are 10-fold lower than *Borrelia burgdorferi* (sensu lato) infection rates in *I. ricinus* in the same areas, although *I. persulcatus* infection rates greater than 10 percent have been reported.[63] The mechanisms underlying this difference are unclear but may include the following[100]:

- The variable infectiousness of the agents and their interactions with modulatory factors in tick saliva
- The relatively brief duration of TBE viremia in animals, which lasts only a few days and thus results in a reduced chance of transmission of virus to feeding ticks, as opposed to the persistent *B. burgdorferi* infections in rodents, with tick feeding more likely to result in infection
- The potential differences in the principal reservoir hosts for the respective infectious agents, with a more limited and focal distribution of important hosts for TBEV, such as goats.

The two agents evidently do not interfere with each other in their infection of *I. persulcatus* ticks; dually infected ticks and singly TBE-infected and *Borrelia*-infected ticks stand in a ratio of approximately 1 : 4 : 14.[63] *I. ricinus* also can be infected with and transmit *Francisella tularensis* and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis.[138]

The geographic distributions of RSSE and European TBE correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation (Fig. 175G-2). New foci are reported periodically as a result of better recognition of the disease, its natural spread, human modifications of the landscape, and environmental and climate changes (e.g., global warming).[29,54,79,107]

EPIDEMIOLOGY

TBE has been recognized in all countries of Europe except Portugal and the Benelux countries, but endemic transmission is most intense in central Europe.[70,107] Human TBE has increased over the last 20 to 30 years in all endemic European countries except Austria, where a well-organized vaccination campaign was initiated.[6,52,79] The incidence of TBE previously ranged as high as 50/100,000 population in Austria, Poland, Hungary, Russia, the Czech Republic, Slovakia, and former Yugoslavia; in certain areas, similar levels of transmission still may prevail. Vaccination has reduced the incidence of disease regionally, especially in Austria, where a national program of immunization since 1981 has reduced the incidence to less than 1/100,000 population.[142] Currently, isolated cases are reported from Norway, Denmark,[128] France,[39] Greece, and Liechtenstein, and fewer than 200 cases are reported annually in Sweden, Germany, and Italy. The Swedish Institute for Communicable Disease Control recently reported the highest annual incidence of human TBE in 2011 and 2012.[52] Switzerland reported a threefold increase in human TBE cases between 2004 and 2006,[143] which resulted both from more infections in endemic areas and from infections in newly recognized foci. Since then, the number of newly diagnosed cases in Switzerland has lowered again, but remained higher than before 2004. In the Far East, cases of RSSE occur principally in forest workers. The disease is recognized in Russia and China, and the first cases acquired in Japan (transmitted by *Ixodes ovatus*) were reported recently.

Within each country, the distribution of cases is highly focal in certain areas and may vary with each year. Local seroprevalence may exceed 20 percent, but the general seroprevalence usually is less than 1/100,000 population. Frequent exposure during long-term residence leads to a general trend of increasing seroprevalence with age. Seroprevalence rates as high as 50 percent have been observed in groups at high risk for exposure, such as farmers and forestry workers. Although, in general, rates are lower (1% to 5%) and in certain groups are similar to the seroprevalence of hantaviruses, lymphocytic choriomeningitis virus, and *Anaplasma* spp., *B. burgdorferi* seroprevalence rates are 10-fold higher or more.[92,98] The frequency of clinical cases of TBE, borreliosis, and dual infection closely approximates the relative frequency of tick infection, singly and dually. Adults 20 to 50 years of age characteristically accounted for most of the cases. In some studies, cases in males (adults and children) predominate by a ratio of 2 : 1.[27,40,78]

Cases have occurred in children as young as 3 weeks,[50,55] but generally, risk in children increases with age as a result of their increased mobility and activity in the sylvatic environment.[78] These epidemiologic patterns are changing in areas with high immunization coverage.[142] Vaccination effort has focused principally on hyperendemic areas and on high-risk occupational groups such as forestry workers. The low number of cases currently reported from areas where vaccination coverage is high belies the continued transmission of virus in these locations.

Cases may be acquired during outdoor activities, such as berry picking and mushroom gathering, and infection occasionally has been acquired from ticks brought from endemic areas on Christmas trees and other objects. One study found that the seroprevalence in Swedish orienteers (1%) was not substantially different from the general seroprevalence in residents of Stockholm County (5%), an area where TBE is endemic. The absence of a higher risk for acquiring TBE in persons with occasional sylvatic exposure reflects the low infection rate of ticks and the generally low risk to persons with sporadic or short-term exposure. Neither of two studies of American

FIGURE 175G-2 ■ The geographic distributions of Russian spring-summer encephalitis and European tick-borne encephalitis correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation.

soldiers stationed in central Europe found a clinical case, although one seroconversion in 3297 person-months of exposure, an infection rate of 0.9/1000 person-months, and four seroconversions in 959 persons (0.4%) were detected.[90,117] With the dissolution of the former Soviet Union and increasing commerce with eastern Europe, interest in the risk for TBE being acquired by travelers to Europe and Russia has increased. The available data suggest that the risk is low for most travelers and that vaccination is not indicated except for unusual circumstances of prolonged stay in an endemic area.

The seasonal distribution of cases lags roughly 1 month behind that of tick activity and extends from April until November. The peak incidence in Sweden is in August; in Austria, the peak occurs in June and July, with a secondary rise in October.

Milk-borne TBE previously accounted for 10 to 20 percent of all cases in central Europe. Infections

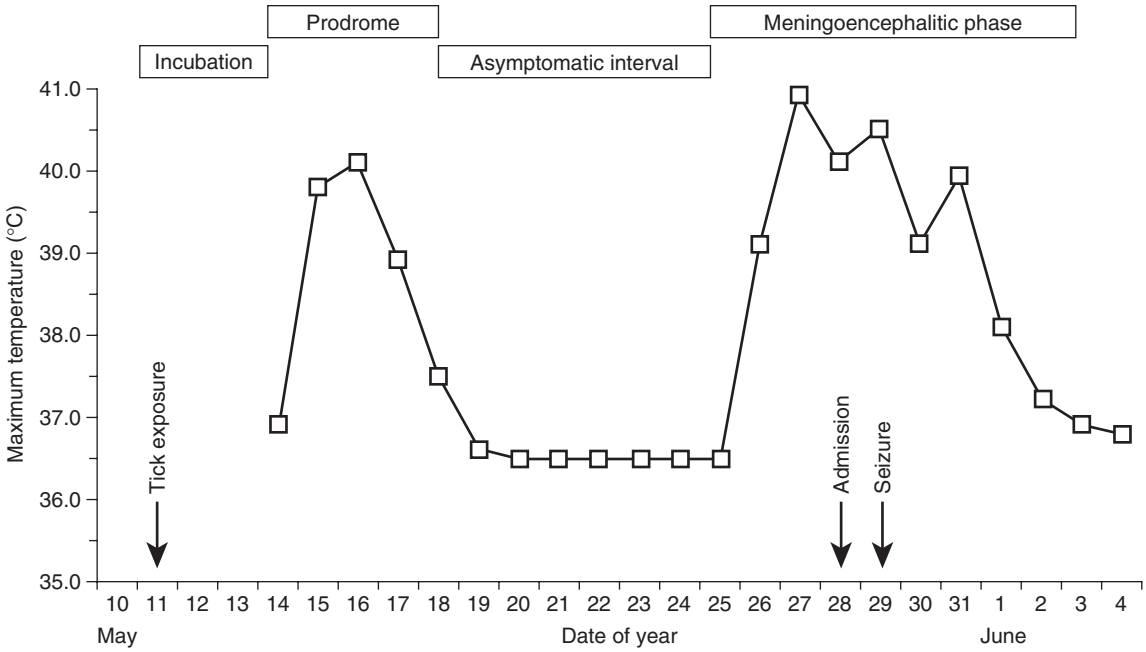

FIGURE 175G-3 ■ Clinical course of tick-borne encephalitis (TBE) in a 5-year-old boy exposed to a tick bite in a known endemic area for TBE in the pre-alpine region of central Switzerland. Lumbar puncture on admission revealed mild cerebrospinal fluid (CSF) pleocytosis (14×10^6/L, 50% polymorphonuclear cells). Serum anti-TBE virus IgM and IgG were present; serum and CSF antibodies against *Borrelia burgdorferi* were absent. CSF enteroviral polymerase chain reaction was negative. Recovery was uneventful.

frequently were acquired from consuming unpasteurized milk or cheese from infected goats, sheep, and cows, and outbreaks resulting in thousands of cases have been reported. Transmission from infected milk now is a rare occurrence, but as recently as 1994, an outbreak in Slovakia led to 7 cases in a group that regularly drank raw milk from a family goat.[63] Also, an outbreak of 21 human cases caused by contaminated cheese produced from unpasteurized sheep milk has been reported.[139] Contact infection, acquired during slaughter of an infected goat, also has been observed.

CLINICAL MANIFESTATIONS

Seroepidemiologic studies indicate that as many as 90 percent of human infections with TBEV remain asymptomatic or result in a nonspecific illness.[2,7,38,59] The classic manifestation of the European form of TBE is an acute febrile illness characterized by a biphasic course consisting of a nonspecific prodromal syndrome followed by central nervous system (CNS) disease (Fig. 175G-3).[34,136] Infection with TBEV may occur solely as the primary, nonspecific phase without the secondary CNS phase.[26,84] Infection with Far Eastern strains of TBEV results in a more severe, monophasic illness that progresses directly to neurologic involvement with a poorer prognosis for survival and full recovery. TBE has been observed in all age groups. The median age in pediatric case series is 8 to 10 years (range, 0 to 17 years).[17,40,78,81,134] The youngest patient with serologically and virologically documented TBE described in the literature was a 17-day-old infant.[55] Congenital infection has not been reported.

The clinical features of TBE in children are summarized in Table 175G-1. The diagnosis of TBE should be considered in all acutely ill patients with fever, CNS abnormalities, and a history of potential tick exposure or ingestion of raw milk in an area endemic for TBE. A high degree of diagnostic awareness is required because the clinical presentation of TBE is nonspecific. After an incubation period of 2 to 28 days, in most cases 7 to 14 days,[27,40,78,81,136] the patient may have a prodromal illness consisting of fever, malaise, nausea and vomiting, headache, myalgia, and, occasionally, upper respiratory tract symptoms.[27,40,65,136] Defervescence occurs after 2 to 7 days, and the patient subsequently remains asymptomatic for 1 to 20 days, usually 2 to 10 days.[27,40,65,78,134] This prodromal illness may be absent. In various case series, a biphasic course was reported in 30 to 90 percent of children with TBE.[40,57,78,81,134] An abrupt onset of fever, headache, emesis, and symptoms of meningeal irritation heralds the beginning of the second phase of disease.[81] In adults, no association exists between the length of the incubation period and the severity of clinical illness.[57] The typical evolution of fever in a child with TBE is shown in Figure 175G-4.

In this second phase of illness, most affected children (50% to 90%) have meningitis without clinical evidence of parenchymal CNS involvement.* In adult patients, by

TABLE 175G-1 **Clinical Features of Serologically Documented Tick-Borne Encephalitis in Five Pediatric Case Series (333 Children)**

Clinical Features	Rate (%)
History	
Tick exposure	47-78
Biphasic illness	77-90
Major Symptoms at Presentation	
Fever >38.0°C (100.4°F)	100
Headache	90-100
Vomiting	60-90
Central Nervous System Signs	
Nuchal rigidity	74-90
Photophobia	10-25
Impaired consciousness	9-11
Ataxia or tremor	5-26
Seizures	0-5
Paresis	0-5
Extent of Central Nervous System Involvement	
Meningitis alone	49-89
Meningoencephalitis	9-48
Meningoencephalomyelitis	0-5
Fatal outcome	0
Cerebrospinal Fluid Parameters	
Pleocytosis >15 × 10^6/L	98-100
Glucose normal	100
Protein elevated	9-55
Abnormal electroencephalogram	80-87

Data from references 16, 36, 52, 74, 76, 127.

contrast, meningitis without encephalitis or myelitis occurs only in 20 to 60 percent of cases.[2,57,65,108,127] On physical examination, fever, signs of meningeal irritation, and photophobia are the most common features.[81,134] In uncomplicated cases, patients defervesce within 5 to 10 days.[40,78,81,134] Meningoencephalitis, meningoencephalomyelitis, or both manifested by impaired consciousness, seizures, and focal neurologic signs, including limb paresis, occurs in 0 to 34 percent of children.* In a large series of 139 pediatric patients with TBE meningoencephalitis, Lesnicar and coworkers[78] observed tremor in all patients, impaired consciousness in 27 (7%), ataxia in 18 (5%), behavioral changes in 16 (4%), cranial nerve paresis in 14 (4%), and limb paresis in 11 (3%). In a series of 13 children, Harasek[40] observed ataxia in 10 patients, somnolence in 4, paresthesias and seizures in 2 each, and central facial palsy and nystagmus in 1 each. In 2 of these patients, transient unilateral shoulder girdle weakness that occurred during the second week of CNS disease suggested involvement of the cervical anterior horn or radiculitis. Overall, limb or cranial nerve paresis occur in 0 to 5 percent of children with TBE (see Table 175-1). In a series of 133 children with TBE, Cizman and colleagues[17] reported transient paresis in 5 patients and irreversible hemiparesis in 1.

In large case series of predominantly adult patients, a paralytic course secondary to bulbar, spinal, or radicular injury was observed in 5 to 25 percent of cases.† Unilateral, flaccid paresis of an upper extremity is the most common manifestation of lower motor neuron disease

*References 17, 40, 57, 78, 81, 134.
†References 57, 61, 90, 127, 131, 136.

complicating adult TBE.[90,131,136] Involvement of the cranial nerves occurs somewhat less frequently and is revealed most commonly by external ocular muscle paralysis (usually cranial nerve VI), peripheral facial palsy (VII), otovestibular manifestations (VIII), or involvement of the pharyngeal muscles (IX, X, and XI).[27,57,90,129] Lower extremity weakness and, occasionally, autonomic nervous system affliction manifested as bladder dysfunction also may occur.[27,58,129] Whereas most manifestations of parenchymal CNS involvement evolve during the acute stage of TBE, paralysis resulting from radiculitis may develop up to 14 days after the onset of CNS disease.[40,70]

As many as 5 percent of children with TBE experience seizures during the acute stage of TBE.[17,40,134] Because most patients are older than 6 years and thus are unlikely to suffer from febrile seizures, these episodes probably reflect encephalitis. In adults, seizures have been observed in less than 2 percent of patients.[27,57]

Extracerebral manifestations of TBE seldom are reported and are of minor clinical relevance. Mild hepatitis[45,57] and electrocardiographic abnormalities have been described in adults.[132] A single case of myopericarditis in a child with TBE has been reported.[28]

The peripheral white blood cell (WBC) count is not altered in a characteristic way. Although it is usually in the normal range, both leukopenia and moderate leukocytosis may be found.[40,81,129] In adult patients, several investigators observed leukopenia during the viremic prodrome and normal or moderately elevated WBC counts during the second phase of illness.[57,65,81,85] In a report describing hematologic values during the prodromal phase of TBE, 23/28 (82%) patients had mild to moderate thrombocytopenia (60 to 130 $\times$ 10^9/L), with values returning to normal during the second phase of illness.[85] Cerebrospinal fluid (CSF) analysis in children with serologically proven TBE reveals predominantly mononuclear pleocytosis in all patients. However, as with enteroviral meningitis, neutrophils may predominate during the first 1 to 3 days of illness.[53] Typically, the CSF WBC count is 100 to 1000 $\times$ 10^6/L.* On occasion, lower values occur, as reported by Krausler and associates,[64] who found less than 100 $\times$ 10^6/L in 24/75 (32%) pediatric cases. Wahlberg and colleagues[136] reported an absence of pleocytosis in 18 percent of 94 adult patients examined. Harasek[40] could not find any correlation between the CSF leukocyte count and the severity of clinical disease. In contrast, some investigators[57,58,61] reported that adult patients with a high CSF white blood cell count (>300 $\times$ 10^6/L) were more likely to experience a severe course of TBE and persistent neurologic sequelae. CSF pleocytosis disappears within 4 to 5 weeks of the onset of acute CNS disease. The CSF glucose concentration is normal,[81] and the protein concentration is normal or moderately elevated (<1000 mg/L),[40,65,81,129] with evidence of dysfunction of the blood-brain barrier in most patients.[58] Electroencephalographic examination findings during acute TBE usually are abnormal and characterized by a nonspecific reduction in rhythmic background activity, bilateral periodic slowing, and, rarely, focal abnormalities.[40,56,57] Attenuation of background activity with periodic delta groups has been shown to correlate with parenchymal CNS involvement in adult TBE patients.[56] Reorganization of electroencephalographic activity commonly lags behind clinical improvement, and abnormalities may persist for months to years.[40,56,134]

The limited information available on magnetic resonance imaging in children with severe TBE indicates that parenchymal lesions characteristically are located in the thalamus (see Fig. 175G-4).[17,57,60,137] The diagnostic and prognostic value of neuroimaging studies in pediatric TBE has not been established. In adults, magnetic resonance imaging studies may detect abnormality in approximately 20 percent of patients.[57] Focal lesions are more likely to be found in those with severe neurologic abnormalities[57] and are confined mainly to the thalamus.* Less frequently, lesions are located in the basal ganglia,[5,57,82,105] cerebellum,[10,57] brain stem,[11,17,57] and anterior portions of the cervical spine.[10,17]

PATHOLOGY

CNS findings are mainly those of acute meningeal inflammation and focal gray matter encephalomyelitis. The white matter rarely is involved. Macroscopic findings include congestion of the leptomeninges and swelling and hyperemia of the cerebral parenchyma, particularly in the brain stem and cervical region of the spinal cord.[35,97] Petechial hemorrhages are seen in the brain stem, the anterior horns of the spinal cord, and, less consistently, the cerebellum and the anterior central region of the cortex. Histologic changes are dominated by infiltration and ganglion cell damage in the gray matter of these same areas. Changes are particularly pronounced in the anterior horns of the cervical spine (consistent with the poliomyelitis-like manifestations of paralytic courses of TBE),[121] the medulla oblongata, the cranial nerve nuclei of the pons, and the Purkinje cell layer of the cerebellum.[35] Inflammatory foci are characterized by lymphocytic perivascular infiltration and various stages of degenerative changes in neuronal cells. Areas of neuronal necrosis are characterized by perifocal edema, lymphocytic and neutrophilic infiltration, and, at a later stage, nodular microglial proliferation at sites of complete neuronophagia. The presence of granzyme, B-expressing, cytotoxic T cells in close contact with TBE-expressing neurons indicates that immune mechanisms contribute to tissue injury in these areas.[32] Rarely, the spinal nerve roots, spinal ganglia, and peripheral nerves are involved. Spongiform changes, particularly after protracted illness, appear as sharply defined areas of softening with minimal inflammatory reaction. In the Far Eastern form of the disease, extensive poliomyelitis of the spinal cord with destruction of anterior horn cells, particularly in the upper cervical and lower lumbar areas, and poliomyelitis of the brain stem are noted.

PATHOGENESIS

Tick-mediated inoculation of TBEV and viral replication within local dermal cells are followed by lymphatic spread to regional lymph nodes, where further replication occurs.[58] Subsequently, viremia leads to generalized infection, especially of reticuloendothelial cells, followed by secondary rounds of viremia that result in neuroinvasion. Viral penetration of the CNS occurs through capillary endothelia and by TBEV-infected, infiltrating mononuclear cells. Envelope glycoprotein E, the immunodominant TBEV-encoded surface protein, mediates attachment to and fusion with the host cellular membrane.[87] The molecular mechanisms of neural invasion by TBEV have not been elucidated in detail. Current knowledge of the molecular pathogenesis of TBEV has been reviewed elsewhere.[41-43]

LABORATORY DIAGNOSIS

Because neither clinical nor CSF findings differentiate TBE from other causes of meningitis or meningoencephalitis, the diagnosis of TBE rests on demonstration of specific antibody by serologic testing. The presence of specific serum immunoglobulin (Ig)M or a significant rise in titer of specific IgG antibody in paired sera (or both) is diagnostic of TBE[48,49,58] unless the patient previously received TBE vaccine doses. Enzyme-linked immunosorbent assay (ELISA) has replaced complement-fixation, hemagglutination-inhibition, and neutralization assays in the routine laboratory diagnosis of TBE.[47,49] ELISA technology offers increased sensitivity, reliably differentiates between IgM and IgG antibodies, and, in contrast to neutralization, uses nonviable viral antigens.[44,112] For the detection of specific anti-TBEV IgM, an IgM-capture ELISA system has proved to be more sensitive and specific than the conventional three-layer ELISA system because high titers of specific IgG and rheumatoid factor do not interfere with IgM binding.[44,112] With this method, specific IgM virtually always can be demonstrated during the acute illness and thereafter may persist for as long as 9 months.[48,58,112] The highly sensitive capture ELISA format allows a determination of anti-TBEV IgM, even in serum samples obtained late during the acute illness, when high titers of specific IgG already are present. A potential problem of TBEV IgG ELISA systems is cross reactivity with other flaviviruses, notably yellow fever virus, dengue virus, and Japanese encephalitis virus.[24,25,99] This limitation should be considered in the interpretation of seroprevalence studies and in patients with a relevant travel or immunization history.

Specific IgM and IgG also can be measured in CSF.[44,112] Detection of TBEV-specific intrathecal antibody production by ELISA is highly specific for the diagnosis of TBE but somewhat less sensitive than is determination of serum IgM during the first several days of CNS disease.[49,58] Intrathecal TBEV antibody assays are less widely used in clinical practice, but they may be useful if serum antibody titers fail to differentiate between infection- and vaccine-induced immunity.

Detection of virus by culture is technically feasible, but it is not used routinely in clinical practice. TBEV can be recovered from blood by viral culture, but because detectable viremia occurs during the prodromal stage (when the diagnosis of TBE seldom is considered), culture is not useful in clinical practice. TBEV may be recovered from the brain tissue of patients who died at an early stage of disease.[18] Amplification of TBEV-specific RNA by reverse transcription–polymerase chain reaction (RT-PCR) has been established for detection of TBEV in ticks, in tick surveys as part of national surveillance systems,[30,106] and, in humans, for individual patient diagnosis[126] Primers that amplify the highly conserved 5′ noncoding region of the TBEV genome have been shown to be sensitive and specific.[125] Successful amplification of TBEV-specific RNA from blood, CSF, or brain tissue has been reported.[19,126,133,137] However, like culture, RT-PCR usually is positive only during the prodromal stage and thus generally is not useful in clinical practice.[55]

DIFFERENTIAL DIAGNOSIS

The clinical course of TBE is nonspecific in most cases, and a history of exposure to ticks in an endemic area can be elicited in 40 to 75 percent of pediatric patients.* Because serologic confirmation of the diagnosis is not available immediately in most cases, the differential diagnosis includes a wide spectrum of diseases causing fever and CNS manifestations.

Enteroviruses are the most common cause of symptomatic CNS infection in children during the warm seasons in regions where TBE is prevalent. Fever in enteroviral infection may occasionally be biphasic,[93] although the duration of both the first phase and the asymptomatic interval usually is shorter than that noted in TBE.[15] Routine tests of CSF do not differentiate between the two entities. Skin and mucosal manifestations are indicative of enteroviral infection rather than TBE, whereas encephalitis and myelitis can occur in both. Enteroviral meningitis is diagnosed most readily by PCR of CSF[118] or by culture of virus from CSF and mucosal surfaces. Mumps meningitis is to be considered in the differential diagnosis in cases without parotid enlargement, particularly in areas with low rates of mumps immunization.[130] The diagnosis of mumps meningitis is made by viral culture of CSF or detection of specific serum IgM antibody. Although it is a rare occurrence in childhood, herpes simplex virus (HSV) encephalitis always should be considered in the differential diagnosis. Because the case-fatality rate of HSV encephalitis is greater than 90 percent if it is left untreated, therapy with intravenous acyclovir should be initiated without delay, if that diagnosis is thought possible. The combination of fever, which may be biphasic,[113] and localizing signs observed by neurologic examination, electroencephalographic studies, or magnetic resonance imaging[51] suggests HSV encephalitis and rarely occurs in pediatric TBE, particularly if the temporal lobe or the orbital portion of the frontal lobe is affected. Meningeal

*References 40, 57, 78, 81, 95, 124, 134.

irritation usually is absent in HSV encephalitis. The diagnosis of HSV encephalitis is confirmed by PCR of CSF.[9,76] Epstein-Barr virus encephalitis can occur in immunocompetent children, and Epstein-Barr virus shares with TBEV a preference for causing thalamic and basal ganglia lesions.[57,102] Other viral causes include common respiratory tract viruses such as influenza, parainfluenza, and adenovirus.

Among bacterial infections, partially treated pyogenic meningitis, encephalitis in association with *Mycoplasma pneumoniae* infection,[115] and encephalopathy caused by *Bartonella henselae* may resemble TBE. Tuberculous meningitis runs a subacute course, and although near-normal CSF chemistry may be recorded very early in the disease, hypoglycorrhachia invariably develops and CSF protein rises to high levels. CNS infection by *B. burgdorferi* is particularly important in the differential diagnosis because in Europe this pathogen and TBEV are transmitted by the same tick vectors—*I. ricinus* and *I. persulcatus*—and because one of the most prevalent European genospecies, *Borrelia garinii*, is more neurotropic than *B. burgdorferi* sensu stricto.[114] In contrast to TBE, the incubation period for early neuroborreliosis in children generally is 4 to 10 weeks, high-grade fever is unusual, and most patients have cranial nerve paresis. However, several cases of concomitant infection with TBEV and *B. burgdorferi* have been reported in the literature,[1,16,66,101] and coexistence of TBEV and *B. burgdorferi* in ticks has been documented.[63] In some cases of TBE, persistent or late-appearing limb paralysis has been suggested to be attributed to concomitant, but undiagnosed, borrelial radiculoneuritis rather than TBE-related myelitis with anterior horn involvement.[66] In this situation, diagnostic evidence of Lyme borreliosis should be sought because this condition requires antimicrobial therapy. Seroepidemiologic and clinical evidence indicates that concomitant infection with TBEV and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis, also may occur.[63,83]

TREATMENT

No specific antiviral therapy is available to treat TBE. However, recent studies suggest tick-borne encephalitis virus is inhibited by LCTA-949, an analog of the antibiotic teicoplanin, and the anthelminthic compound ivermectin.[22,89] In severe cases, supportive therapy is aimed at preventing the development of sequelae related to increased intracranial pressure, seizures, and bulbar dysfunction. After the acute stage, neurorehabilitation may be necessary for patients with motor, cognitive, or emotional disturbances. Because TBE rarely causes a chronic seizure disorder, prolonged anticonvulsive therapy seldom is indicated in patients who had convulsions during acute disease.

PROGNOSIS

The main risk factor for neurologic residua and a fatal outcome of TBE is advanced age.[2,57,127] Substantial sequelae appear to be infrequent in children,* although no prospective long-term follow-up studies of pediatric TBE patients have been performed to date. Individual cases of children, presenting more likely with meningoencephalitis in the acute phase, show persistent neurologic damage, including hemiparesis,[17,55,60,137] unilateral arm paresis,[136] epilepsy,[55,60,111] and extrapyramidal movement disorder.[60] Recent evidence, however, indicates that subtle abnormalities in attention and psychomotor skills may persist in many children for prolonged periods.[122] In adult patients, long-term neurologic defects are observed in 2 to 10 percent of patients with clinical evidence of parenchymal CNS involvement during the acute illness.[2,34,57,61,136] Risk factors for persistent sequelae have been assessed by Kaiser[57] and, by univariate analysis, include impaired consciousness (i.e., Glasgow Coma Scale score <7), ataxia, paresis, abnormal findings on magnetic resonance imaging, CSF pleocytosis greater than 300×10^6/L, and CSF protein concentration of more than 600 mg/L. Gunther and colleagues[37] reported that encephalitic symptoms were associated with low levels of intrathecal IgM in early stages of TBE. Paresis of the extremities and ataxia are the most common persistent findings on neurologic examination.† Much more common, however, are ill-defined manifestations such as chronic fatigue, headache, sleep disorders, memory dysfunction, and emotional disturbances, which are reported by most adults recovering from TBE and persist for months to years.[27,77,127] In some patients, electroencephalographic findings may remain abnormal for prolonged periods, with seizure activity occasionally demonstrated.[40,122] Most of these patients are asymptomatic, although epilepsy secondary to TBE has been described infrequently.[40,96] The reported case-fatality rate in adult TBE patients is approximately 1 percent in large series,‡ with most deaths being attributed to severe bulbar encephalitis or related to underlying cardiovascular disease in elderly patients.[27] Fatal outcome of TBE in children is exceedingly rare.[91]

PREVENTION

General preventive principles include avoidance of known endemic areas of TBE, use of protective clothing, and rapid removal of ticks attached to the skin. The topical repellent *N,N*-diethyl-*m*-toluamide (DEET) has a definite albeit moderate effect against ticks.[116] Because of its potential neurotoxicity, the content of DEET in products used for children should not exceed 15 percent.[13,103] These measures are effective in reducing tick exposure and transmission of TBEV to some degree. Pasteurization of raw milk prevents enteric transmission of TBEV.[4,62]

Reliable protection, however, requires active immunization against TBE. Inactivated whole-virus vaccines are produced in Austria (Baxter), Germany (Chiron), and Russia. The vaccines are made from different central

*References 40, 57, 68, 81, 122, 134.

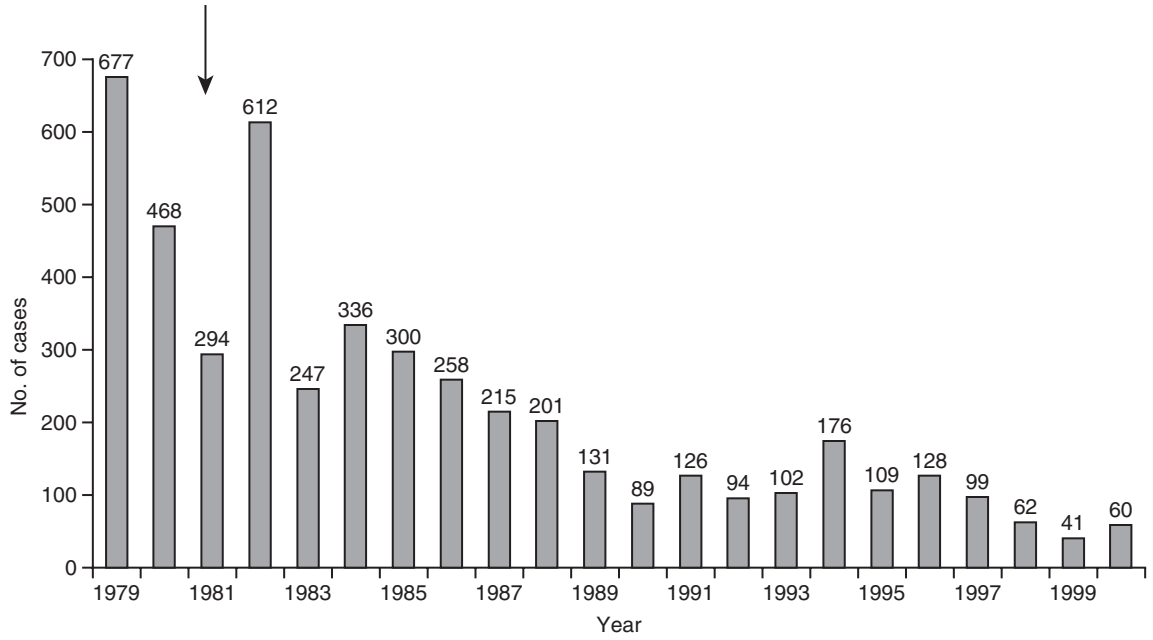

FIGURE 175G-5 ■ Annual number of cases of tick-borne encephalitis in Austria before and after the introduction of mass immunization in 1981 *(arrow).* (Data obtained from the International Scientific Working Group on Tick-Borne-Encephalitis, http://www.tbe-info.com/report.)

European TBEV strains and are produced by concentrating and purifying cell culture fluid from infected chick embryo cells. Adjuvants (aluminum hydroxide) are added to the formalin-inactivated cell culture fluid. The Russian vaccine is an inactivated, unconcentrated cell culture fluid from infected African green monkey kidney cells. TBE vaccine is available in the United States under investigational drug exemption to military personnel deployed in endemic areas.[12,20]

Currently approved TBE vaccines are approved for children 12 months of age and older. Basic immunization consists of three doses given at 0, 1 to 3, and 5 to 12 months. Rapid immunization schedules also are available. The vaccines are immunogenic and safe.* Seroconversion rates for neutralizing antibodies after the first, second, and third dose are 70, 95, and 99 percent, respectively.[69,73] Reliable protection is achieved 2 weeks after administration of the second dose.[141] Data on the kinetics of vaccine-induced serum antibodies led to the first recommendation for booster doses every 3 years.[69,71] Recent data on the decay of neutralizing antibodies, however, indicate that protection may last considerably longer[109,110]; therefore, booster doses are recommended only every 5 to 10 years in some European countries. Minor adverse events (i.e., fever and local reactions) are reported by 4 to 15 percent of vaccinees after receiving the first dose and less frequently after receiving subsequent doses.[71,104,140] Mostly transient neurologic adverse events temporally associated with the administration of TBE vaccine have been reported rarely.[33,34,119,120,123] Their true incidence has not been established. Based on passive notification of adverse events, an incidence of one neurologic illness in 1 million doses of TBE vaccine has been calculated.[46] Placebo-controlled trials of vaccine efficacy have not been conducted. Observational studies in Austria using historical controls indicate that the effectiveness of the vaccine is greater than 90 percent.[72,75]

In Austria, the TBE vaccine is recommended for mass immunization of all potentially exposed individuals. Since the beginning of the vaccination campaign in 1981, a dramatic reduction in nationally notified cases has been observed (Fig. 175G-5).[75,142] Mass immunization is the probable cause of this decrease because neighboring countries (e.g., Switzerland, southern Germany, and Slovenia) reported stable or increasing numbers of cases of TBE during the same time. In these and other endemic countries of central and eastern Europe, authorities recommend immunization of school-aged children and adults who live in endemic areas and have a risk for exposure to ticks.[17,98] In younger children, TBE vaccination is not recommended routinely because neurologic complications are exceedingly rare.[17,78]

Specific IgG has been used exclusively for passive immunization within 96 hours of exposure to ticks in endemic regions. Because of reports from some patients[3,74] who developed a severe form of TBE disease after immunoglobulin administration, these products have been withdrawn in many countries. These severe cases raised concern about a causative role of TBE immunoglobulin in enhancement of disease.* Antibody-dependent enhancement, a mechanism of pathogenicity proposed in dengue hemorrhagic fever,[94] was discussed as a possible explanation,[60] but experimental data in support of this hypothesis in TBE are lacking.[60]

175H ■ OTHER FLAVIVIRAL INFECTIONS

Theodore F. Tsai

POWASSAN ENCEPHALITIS

Powassan virus was isolated from a fatally infected patient and named after the patient's Ontario town of residence.[7] The virus is classified within the antigenic complex of tick-borne flaviviruses, with North American viruses circulating in two genetic lineages in distinct enzootic cycles.[9] More than half of surviving cases suffer from residual neurologic deficits, frequently associated with upper cervical damage leading to upper extremity muscle weakness and wasting.

Epidemiology and Ecology

Fewer than 50 sporadic cases of naturally acquired Powassan encephalitis have been reported from North America and others from Russia, as well as two laboratory-acquired cases. Approximately one fourth of the cases from North America have occurred in children younger than 15 years, and the preponderance of cases have been in males. Most cases have occurred in the summer or early fall, and one patient had an onset in December.[14,30]

Reported cases have been acquired chiefly in eastern and upper midwestern U.S. states and Canadian provinces; however, the geographic distribution of the virus is far wider, with strains recorded from West Virginia, Colorado, South Dakota, and California, and serologic evidence of infection in humans or animals reported from Wyoming, North Dakota, British Columbia, Alberta, and Sonora, Mexico.[9,20] Viral isolates also have been recovered from ticks, mosquitoes, and birds from southeastern Russia, and evidence of viral transmission in China and Southeast Asia has been reported.[26]

In North America, viruses in lineage 1 are transmitted to small mammals by *Ixodes cookei* ticks, chiefly to groundhogs, skunks, and weasels; by *Ixodes marxi* ticks mainly to red squirrels; and by *Dermacentor andersoni* ticks to chipmunks.[9] The virus is transmitted trans-stadially in *D. andersoni* and *Ixodes pacificus*, and transovarial transmission has been shown in other species. Lineage 2 viruses (deer tick virus) are transmitted by *Ioxdes scapularis;* however, although infections have been demonstrated in *Peromyscus* mice, details of the viral transmission cycle are poorly defined. Because *I. scapularis* also is the vector of *Borrelia burgdorferi*, *Babesia microti*, and *Anaplasma phagocytophilum*, it is of interest that in a collection of adults ticks from Long Island and Westchester County, New York, 2 percent were infected with Powassan virus, whereas infection rates for the other pathogens were 64, 20, and 20 percent, respectively.[38] The absence of a Powassan epidemic paralleling that of Lyme disease suggests differences in the agents' transmission cycles. Because the deer tick virus has been implicated in two fatal Powassan encephalitis cases, it seems unlikely that the strain is less virulent to humans than lineage 1 strains.[14,37] Russian strains of the virus are identical to lineage 1 viruses, suggesting an introduction from North America within the last century, possibly with the importation of farmed minks.[23] *Ixodes persulcatus* and various *Haemaphysalis* ticks are the principal vectors and *Apodemus* mice and *Microtus* voles are the main vertebrate hosts.

Seroprevalence in humans is low, from less than 1 percent to 3 percent. Human infections probably are rare because *I. cookei* ticks usually confine themselves to animal host burrows, limiting opportunities for human exposure. Patients usually give a history of outdoor exposure but, in one case involving a 13-month-old infant, an infected tick was brought into the home by a domestic cat.[41] Animal serosurveys indicate that infections occur in dogs, and exposure to ticks on domestic animals may be an alternative source of infection. In a survey of New York goats, 2 percent had serologic evidence of past Powassan virus infection, which indicates the possibility of raw milk-borne Powassan virus infection in the United States, similar to the alimentary transmission of tick-borne encephalitis from infected raw milk products in Europe.[43] Although no such cases of Powassan cases infection have been reported, experimental studies have shown that domestic goats can be infected with Powassan virus and can shed the virus into milk.

Clinical and pathologic signs of encephalitis have been produced in experimentally infected horses. Unlike Lyme disease and some rickettsial infections, Powassan virus infection can be transmitted after a brief period of tick attachment.[10]

Clinical Manifestations

The incubation period may be several weeks after known exposure to a tick. Early symptoms of fever, headache, lethargy, vomiting, retro-orbital pain, and photophobia are followed by changes in sensorium, confusion, generalized or focal seizures, paresis, and paralysis, that may lead to coma and require ventilator support and intensive care.* Magnetic resonance imaging has shown restricted diffusion and abnormal enhancement in parietal and temporal lobes and thalamic hemorrhage, which is often seen in other forms of flaviviral encephalitis. Approximately 10 percent of cases have been fatal; however, significant neurologic sequelae follow in the majority of survivors, including hemiplegia, quadriplegia, aphasia, and cognitive impairment. Residual shoulder girdle atrophy and weakness analogous to sequelae that occur after European and Far Eastern tick-borne encephalitis, are common.[5] In another patient, wasting and weakness of a leg consistent with lumbosacral poliomyelitis were reported.[7,21] On the other hand, a laboratory confirmed case was reported in a febrile patient without neurologic signs.[20]

Clinical and experimental observations of tick-borne encephalitis suggest that chronic central nervous system infection characterized by a seizure disorder (i.e., epilepsia partialis continua), weakness, and dementia may occur after recovery from the acute phase of illness. A retrospective study of 22 Canadian patients with a similar clinical syndrome and in whom histologic changes in the brain resembled those of chronic tick-borne encephalitis showed no evidence of Powassan virus infection. However, none of these patients had a history of acute encephalitis.

Laboratory Diagnosis

Virus has been recovered from the brains of patients with fatal cases of the disease. A serologic diagnosis can be achieved more rapidly by detecting specific immunoglobulin (Ig)M antibody in acute-phase serum or spinal fluid. Heterologous antibodies from other flavivirus infections (e.g., dengue and West Nile and St. Louis encephalitis) or vaccinations (e.g., tick-borne encephalitis and yellow fever) may interfere with interpretation.

Differential Diagnosis

The clinical findings of encephalitis in a patient with a history of a tick bite acquired in an endemic area should suggest the possibility of Powassan encephalitis. However, because ixodid tick bites may be inconspicuous, a negative history does not exclude the diagnosis. Other viral agents of encephalitis, especially eastern equine encephalitis virus and California group viruses, which are prevalent in New York State and eastern Canada, should be considered in the differential diagnosis. Lyme disease, because of its known geographic distribution and association with a tick vector, also may be associated with neurologic complications; however, a history of having a typical rash and arthritis should differentiate the conditions. In a series of 145 clinical encephalitis cases at a Canadian tertiary pediatric hospital, one was attributed to Powassan virus.[22] Imported travel-associated cases of tick-borne encephalitis acquired in Europe have been reported, underscoring the value of obtaining a travel history.

Treatment and Prevention

No specific therapy for Powassan encephalitis is available. Personal protective measures to avoid tick bites are advised. Consumption of unpasteurized goat milk should be avoided because of the theoretical risk for contracting Powassan virus infection and the well-documented risk for acquiring other infections associated with raw milk. Inactivated tick-borne encephalitis vaccines licensed in Europe do not cross protect against Powassan virus infection.

ROCIO ENCEPHALITIS

Rocio encephalitis virus was isolated from the brain of a fatal case of encephalitis in a patient during an outbreak in 1975.[12,24] The virus is antigenically to viruses in the Japanese encephalitis virus complex. The disease has been reported exclusively in São Paulo State and adjacent Paraná State, Brazil, principally in the Ribiera Valley and Santista lowlands. More than 1000 cases were documented in outbreaks between 1975 and 1977; only one symptomatic case (in an infant) has been recognized subsequently, although recent infections (IgM in asymptomatic individuals) were documented in later serosurveys in northeastern and southeastern Brazil. Thus, the virus may be transmitted undetected in an area beyond the Ribiera Valley. The viral transmission cycle has not been elucidated; however, field and laboratory observations suggest transmission between birds and *Psorophora* or *Aedes* mosquitoes. Humans are dead-end hosts. Human cases have occurred principally in men with outdoor occupations, especially fishermen.

The incubation period is estimated to be 7 to 14 days. Prodromal symptoms of fever, headache, malaise, vomiting, and conjunctivitis are followed by mental status changes, meningismus, and motor impairment. Cerebellar signs occur commonly. Signs of bulbar involvement also are seen. Coma and a fatal outcome occur most commonly in children (30%) and in seniors; overall, 10 percent of cases are fatal and 20 percent of patients have had neuropsychiatric sequelae. Pathologic findings of encephalitis principally involve the thalamus, cerebellar dentate nucleus, brain nuclei, brain stem, and spinal cord.

The diagnosis should be suspected in patients with acute encephalitis acquired in South America. The

*References 4, 7, 11, 14, 16, 19-21, 30, 34, 36, 37, 41.

presence of virus-specific IgM in cerebrospinal fluid or a fourfold change in serum antibody titer confirms a case, but cross reactions with St. Louis encephalitis, dengue, and other flaviviruses should be ruled out. Treatment is supportive. Emergency application of adulticides and larvicides has been used to control epidemics.

LOUPING ILL VIRUS

Louping ill virus derives its name from an old Scottish term describing the leaping motions of encephalitic sheep. Historical accounts of the disease in sheep date from 1795, and the virus was isolated in 1931. The virus is a member of the antigenic complex of tick-borne flaviviruses and is transmitted by *Ixodes ricinus* ticks.[6,15,28] Sheep, deer, mountain hares, and grouse are the principal amplifying hosts. Grouse may become infected by ingesting infected ticks. The disease is enzootic in pasturelands of Scotland, England, Wales, and Ireland, where human infections have occurred mainly in sheep farmers, veterinarians, and abattoir workers or butchers who had direct contact with animals or their meat. Antibody prevalence is 10 percent in abattoir workers in enzootic areas. Laboratory-acquired infections are common and account for half of all reported human cases. These observations suggest that infections are transmitted easily by direct mucous membrane or respiratory infection. Hospital surveillance in an enzootic area found louping ill virus to be a rare occurrence that was responsible for fewer than 0.5 percent of encephalitis cases. Related tick-borne viruses in Spain, Greece, Norway, and Turkey have not been associated with human disease. The virus is shed in sheep and goat milk, but unlike tick-borne encephalitis, milk-transmitted cases have not been reported. Sheep in the United Kingdom are routinely vaccinated with a crude inactivated vaccine.

The incubation period can be as short as 3 days. Three clinical syndromes have been described.[6] Approximately a third of patients have a self-limited influenza-like illness with fever, headache, dizziness, and myalgias. The febrile illness is followed by clinical improvement and a second encephalitic phase in more than half of the cases. Neurologic symptoms include meningismus, severe headache, vomiting, drowsiness, and tremor; one fatal case was reported. A poliomyelitis syndrome with muscle weakness or paralysis has been described in a few cases; the final presentation is hemorrhagic fever, which was reported in one atypical laboratory-acquired case.

The diagnosis should be suspected in febrile patients with occupational or other exposure, especially if central nervous system symptoms are present. The diagnosis can be confirmed by polymerase chain reaction or, serologically, by demonstrating virus-specific IgM in cerebrospinal fluid or serum or by a fourfold rise in antibody titer. Treatment is symptomatic. Consumption of unpasteurized milk products should be avoided. Persons with outdoor exposure in enzootic areas are advised to use repellents and other protective measures against tick bites. Licensed human vaccines against tick-borne encephalitis virus are likely to be protective.

KYASANUR FOREST DISEASE

Kyasanur Forest virus was isolated in 1957 after an outbreak of hemorrhagic fever, initially suspected to be the first outbreak of yellow fever in Asia, appeared in India in the Kyasanur Forest of Mysore (now Karnataka).[2,31-33] The virus subsequently was identified as a member of the tick-borne flaviviral antigenic complex and shown to be transmitted by *Haemaphysalis spinigera* (among numerous other ixodid ticks). Forest rodents, insectivores, and possibly bats, participate in the transmission cycle, and Langur monkeys sicken in epizootics and die of the infection. Human cases occur in dry-season epidemics, chiefly in persons who have contact with tick-infested forests. The disease has spread geographically as villagers clear forests for pastureland. Between 1982 and 1988, 1847 cases were reported, 254 of which were fatal.[31] Hyperendemic transmission in Karnataka State continues despite the introduction of mass vaccination with a locally produced, inactivated chick embryo fibroblast–derived vaccine.[31] The geographic distribution of the virus is now known to be much broader, with virologic or serologic evidence of infection throughout China and on the Andaman and Nicobar Islands.[40]

Additionally, a viral variant of the virus that has caused outbreaks of hemorrhagic fever in Saudia Arabia, Alkhumra virus, was transmitted to Italian tourists visiting the Egypt–Sudan border, indicating a distribution possibly encompassing a broad swath of Northern Africa, the Middle East, and into Central, South, and East Asia.[4,27] Molecular epidemiologic studies support the ancestral eastward spread of tick-borne flaviviruses, possibly along camel trade routes or by migrating birds carrying infected ticks.[18] Alkhumra virus has been acquired principally by persons who had close contact with livestock animals or their meat during or after slaughter, although mosquito-borne transmission from infected animals also has been suspected.[27] Tick-borne transmission was strongly suspected in the case of the Italian tourists.[4]

After an incubation period of 3 to 8 days, illness begins abruptly with fever, headache, myalgias, chills, and gastrointestinal symptoms.[2,32,33] Patients are seriously ill with facial hyperemia, conjunctival suffusion, lymphadenopathy, and hepatomegaly, and they may be bradycardic and hypotensive. A papulovesicular enanthem and petechiae are seen, and mucosal bleeding from the gums, epistaxis, hemoptysis, and gastrointestinal and vaginal bleeding may be prominent. Bronchopneumonia and hemorrhagic pulmonary edema complicate the illness in 40 percent of cases. Renal failure may develop. After the resolution of symptoms and an afebrile interval of 1 to 3 weeks, fever, recurrence of symptoms, and meningoencephalitis develop in 15 to 50 percent of cases, as occur in tick-borne encephalitis. Although biphasic febrile illness also occurs in patients infected with Alkhumra virus, encephalitis, which complicates one fourth of cases, usually is a component of the primary illness.[27] Leukopenia with a left shift, thrombocytopenia, and an elevated hematocrit reflecting hemoconcentration are seen, and, in some cases, evidence of disseminated intravascular coagulation. Elevations in liver enzymes are present in the majority of

cases. The case-fatality rate is 3 to 15 percent. Keratitis and iritis have been reported to occur as sequelae. The virus frequently can be isolated from acute-phase blood specimens (<12 days after onset), or the diagnosis can be confirmed serologically.

OMSK HEMORRHAGIC FEVER

Omsk hemorrhagic fever virus was isolated from a viremic human during a series of outbreaks in the Omsk region of western Siberia from 1945 to 1949.[25,35] Between 1945 and 1958, approximately 1500 cases were reported in the forest-steppe zones within the Omsk, Novosibirsk, Kurgan, and Tjumen regions; however, the distribution of enzootic and human infections has shrunk considerably and human cases now are reported sporadically only from Novosibirsk. The virus is related antigenically to other tick-borne flaviviruses and is spread by *Dermacentor marginatus*, *Dermacentor reticulatus*, and *I. persultcatus* ticks that may be dually infected with tick-borne encephalitis virus. Numerous small mammals, especially *Microtus* voles, are infected in the transmission cycle, but it was the introduction of muskrats *(Ondatra zibethicus)* into the region from Canada in the early 20th century that resulted in an expansion of viral transmission and large outbreaks in trappers, despite high mortality in the infected muskrats. Seasonal peaks of infection are in May to June and August to September, but recent cases, occurring principally among hunters and trappers, occur through the end of the year. Infections are transmitted by tick bites, directly from infected muskrats during skinning, and potentially from streams where the virus survives for months after being shed by infected animals. Alimentary infection from consumption of infected goat milk is possible but has not been reported. Laboratory-associated cases frequently have occurred. The incubation period may be as brief as 2 to 4 days. The illness is similar to Kyasanur Forest disease, but with an earlier onset of hemorrhagic phenomena (e.g., epistaxis). Hemorrhages tend to be less severe, and the overall mortality rate is lower (<3%). A second phase of illness develops after an asymptomatic period of 1 to 2 weeks in 30 to 50 percent of cases and frequently is dominated by neurologic symptoms. Cases coming to attention at that point can be diagnosed only serologically. Vaccine produced against tick-borne encephalitis virus is reported to provide some degree of cross protection.

ZIKA FEVER

Although Zika virus was described to cause sporadic acute febrile infections in Uganda in 1947, only sporadic cases of the self-limited fever, usually accompanied by a maculopapular rash and arthralgias were reported from Africa and Asia until an explosive outbreak occurred on the Micronesian island of Yap in 2007.[8,17] More than 70 percent of the island's population was infected, and, in addition to the previously described symptoms, conjunctivitis featured prominently in the cases. The virus is transmitted by many of the same forest and urban vectors as yellow fever virus, and in this outbreak *Aedes hensilli* was strongly suspected to be the vector. The means by

which the virus was introduced to the island are unclear, although introduction by a viremic traveler is possible—a mechanism that was underscored when two entomologists returned to the United States from Senegal while incubating the illness and fell ill after arriving home.[13] One of the index cases then transmitted the infection directly to his partner, possibly venereally. The nonspecific febrile illness should be considered in the differential diagnosis of dengue and other tropical fevers.

OTHER FLAVIVIRAL INFECTIONS

Flaviviral infections of lesser public health importance or that are recognized less frequently are listed in Table 175H-1.[1,3,26,29,42] Several of the viruses are known to cause human illness only after laboratory exposure, and others, like Usutu virus, have been reported to cause illness only in highly immunocompromised patients.[39] The clinical manifestations of these infections may differ from naturally acquired infection because of their mode of transmission by respiratory, mucosal, or other routes of infection. Other viruses that cause nonspecific syndromes of febrile illness were discovered through fever surveys; although few cases may have been reported, their prevalence may be underestimated because few cases are recognized.[1,3,26,29,42] Because immune responses to repeated flaviviral infections lead to broadly cross-reactive responses, serologic diagnosis may be misleading unless extensive cross-neutralization assays are undertaken. Of the zoonotic flaviviruses (transmitted from animal to animal without an arthropod vector), only Rio Bravo and Modoc viruses are known to cause human illness.

HISTORY

After reliable testing for both hepatitis A and B was developed, it became clear that a significant number of bloodborne, transfusion-related cases of hepatitis existed. These patients appeared to be infected with an agent that tested negative for both hepatitis A and B and thus was deemed "non-A, non-B hepatitis." The agent was suspected to be viral because transfer of blood from affected patients into naïve chimpanzees resulted in hepatitis. After a great deal of effort, the virus was finally identified in 1989.[25] A group at Chiron used molecular methods to identify RNA sequences from infected chimpanzees that were distinct from any known virus. HCV was the first pathogen to be described using only molecular methods, a practice that has now become the standard form of pathogen discovery. After a great deal of validation work, they named the virus hepatitis C virus.[63]

VIROLOGY

HCV is classified in its own *Hepacivirus* genus within the Flaviviridae family.[68,102] It is an enveloped single-stranded, plus-sense RNA virus organized into one long open reading frame of approximately 9500 nucleotides.[69] It has the structural protein genes at its 5′ end and its nonstructural proteins toward the 3′ end.[35,95] Figure 176-1 illustrates how the HCV genome is organized and lists the names of individual genes and their main role during infection. The details of the molecular and structural biology of HCV are reviewed elsewhere,[35,69,95] but several unique features of the HCV genome are worth noting here. The HCV RNA 5′ untranslated region (5′UTR) contains an internal ribosomal entry site (IRES), a feature that no other flavivirus contains.[28] The IRES allows for direct binding of host ribosomes to the viral RNA using a set of proteins different from those required for conventional capP-dependent translation. The 3′UTR does not feature a poly-A tail as many flaviviruses do.[35] The HCV E2 protein contains a hypervariable region that responds to immune-mediated pressure with hypermutation.[35] The resulting "quasispecies" of HCV allow for rapid escape of antibody neutralization in a fashion very similar to that observed with human immunodeficiency virus (HIV), with the similar effect of making vaccine development a difficult proposition.[45] The HCV NS3 is a multifunctional protein, with both helicase and protease domains.[68,69] The HCV NS5A protein is an important cofactor for many viral processes, including RNA replication and viral assembly.[68,69] The HCV NS5B is the RNA-dependent RNA polymerase.[68,69]

In vitro systems used to study HCV include subgenomic replicons, which are RNA constructs containing only the nonstructural region of the virus that can replicate themselves but produce no functional virus.[13,70] Pseudoviruses using a retrovirus or Semliki Forest virus as a backbone have been used to study virus-receptor interaction.[12,46] In 2005, a one-of-a-kind isolate of HCV was discovered in Japan, deemed "JFH1," which was found to replicate in vitro and produce infectious virus

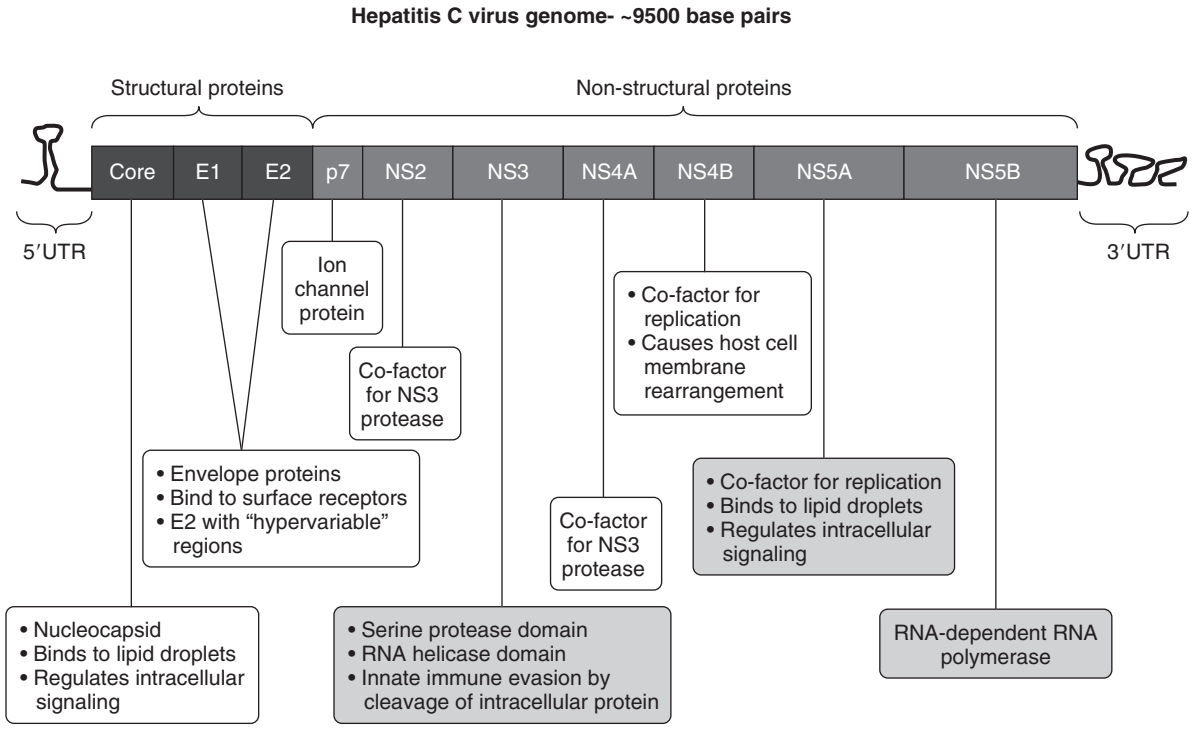

FIGURE 176-1 ■ Genomic organization of hepatitis C virus (HCV). HCV is organized as a single open reading frame coding for one polyprotein that is subsequently cleaved into multiple individual proteins. Structural proteins are shaded in *dark gray,* nonstructural proteins in *light gray.* The name and most important functions of each protein are provided. Proteins that serve a current or near future direct antiviral targets are indicated by a *shaded* function box.

in several liver cell lines.[126] This discovery has since allowed for incredibly rapid progress in understanding the HCV viral life cycle.

HCV exists in the bloodstream in several different forms: "naked" virus, which would be the enveloped virus alone; HCV bound to antibody in higher density fractions; HCV bound to low-density lipoproteins (LDL) and very-low-density lipoproteins (VLDL).[3,6,7] These last two fractions are deemed "lipo-viro-particles" (LVPs) and have been shown to be the most infectious form of HCV.[3,7,11,39]

PATHOGENESIS

After gaining access to the bloodstream, the virus targets the liver by poorly understood mechanisms. Receptor density as a potential contributing factor was discussed earlier.[68,100] The virus replicates within the infected cell but does not cause cytolysis.[68,69] HCV replicates to very high levels within liver cells, and a significant proportion of the virus is released into the bloodstream. The exact levels of virus in the liver are unknown.[65] At some point that differs from patient to patient based on age, genetics, and other host factors, the interaction among virus, host liver cells, and host immune cells results in either resolution of infection or progression to chronic infection.[24] Resolved acute HCV has no long-term consequences. During chronic infection, inflammatory signals are released from the infected cells that, over time, contribute to the fibrosis and necrosis that is observed with long-standing infection.[111]

Viral Life Cycle

HCV has been shown to interact with several proteins that serve as primary receptors or coreceptors depending on whether it is the initial infection or whether cell to cell spread has occurred within an already infected liver. The first interaction appears to be when LVPs interact with the scavenger-receptor B1 (SR-B1) protein.[18] This interaction is not required, and other lipid-related proteins such as the low-density lipoprotein receptor (LDLR) may substitute for SR-B1.[84] Given the enrichment of these proteins on liver cells, this step likely provides much of the tissue specificity for the virus. After this initial binding step, a more specific interaction takes place between the HCV E2 protein and the CD81 molecule.[59,133] This interaction is thought to be a critical one for initial infections. This E2-CD81 complex then traffics to the tight junction of the cell, where interactions with both tight junction proteins claudin-1 and occludin-1 mediate the final steps in viral entry.[33,43,97] It has been shown that for direct cell to cell spread, the tight junction proteins can mediate infection alone, bypassing the need for CD81 or SR-B1.[121]

After cell entry, HCV relies on a specific interaction with a liver-specific microRNA, miR-122, as a necessary cofactor.[56] The HCV RNA has two sites in the 5′UTR that are complementary to miR-122.[55] This is the first instance of a microRNA enhancing the function of an RNA, because in almost every other circumstance, microRNAs serve to silence gene expression by causing degradation of mRNA.

Another key step in the HCV life cycle is the association of the core protein with lipid droplets as part of viral assembly and release.[15,82] When first discovered, this was unique among flaviviruses, although it is now understood that dengue virus also associates with lipid droplets.[107] When bound to lipid droplets, the core protein recruits other viral proteins and newly synthesized RNA to form new virions.[82] Disruption of this association prevents the release of infectious virus.[15,112] HCV has evolved to co-opt many host lipid synthesis and trafficking pathways—binding to lipid droplets, requiring several apolipoproteins for assembly, and using VLDL export pathways for viral release.*

EPIDEMIOLOGY

The epidemiology of HCV varies significantly based on age and geography. In the general U.S. population, approximately 4 million have HCV antibody–positive status and approximately two-thirds of those have chronic infection.[5,8] In children, between 0.1 and 0.4 percent have evidence of HCV antibody.[5,31] These studies were performed before major demographic shifts in the U.S. population over the last decade, so these rates may have increased.

Certain countries are known to have exceedingly high rates of HCV seroprevalence, largely as a result of unsafe injection practices and a contaminated blood supply. Pakistan is known to have HCV seroprevalence rates of 4 to 10 percent.[61,124] In Egypt, 10 to 15 percent of the general population, including children, have HCV antibody–positive status.[1,113] This the highest rate in the world and is largely due to widespread inoculation of many individuals during a public health intervention to control schistosomiasis.[1] After screening for the parasite in the stool and urine, patients were treated with an intravenous tartar preparation.[116] Needles used during these treatments were not sterile during the approximate 20-year period when these practices were in place. Once oral praziquantel replaced the intravenous treatment, the rates of HCV infection from this intervention were reduced significantly. However, the seroprevalence in the population was already high and other modes of transmission serve to perpetuate the epidemic.[83,96]

VIRAL GENETICS

HCV has six major genotypes of HCV that very in their geographic distribution.[35,80,115] Genotypes 1a and 1b are the most prevalent genotypes in the United States and Western Europe. Genotypes 2 and 3 are minority genotypes in this region, but are more frequently observed in Asia and Australia. Genotype 4 is frequently observed in Africa, particularly in Egypt. Genotypes 5 and 6 are minority genotypes, mostly in Africa.

*References 7, 11, 49, 58, 82, 106, 112, 114.

The different genotypes are associated with important clinical phenotypes. Response to interferon (IFN)-based therapy varies widely based on genotype.[36] Genotypes 2 and 3 are exceedingly responsive to IFN, with sustained response rates between 80 to 90 percent. Genotypes 1a, 1b, and 4 all respond to IFN at much lower rates, closer to 40 to 50 percent. Genotype 3 is associated with more frequent and more severe steatosis (fatty liver) in contrast to other genotypes.[48,92]

TRANSMISSION

HCV is transmitted efficiently by exposure for blood and blood-containing solutions, tissue, and equipment.[68,130] Before effective tests for screening blood and blood products in the early 1990s, virtually all patients dependent on regular transfusions, such as hemophiliacs and those with hemoglobinopathies, became chronically infected with HCV.[4,128] In the current era, in which blood supplies are rigorously screened, the primary route of bloodborne transmission is among injection drug users. Nosocomial transmission from medical and dental equipment is a constant issue that manifests when intentional and unintentional breach of sterile techniques occur.[19,21,22,103,118]

For children, the major route of transmission is mother to infant (vertical transmission).[9] It is clear that only mothers with active viremia will transmit HCV, but beyond that, no clear risk factors for transmission have been defined.[20,74,101,113] Although higher viral loads increase risk, no threshold level has been defined. Caesarean section has not been demonstrated to be protective of transmission.[19,32,74,79] Studies from countries with different prevailing genotypes demonstrate comparable rates of transmission.[20,74,113] Overall transmission rates vary between 5 and 10 percent depending on the study. In the era before highly active antiretroviral therapy (HAART), HIV coinfection raised the vertical transmission rate to 20 to 25 percent.[89,101,120] However, in the current HAART era, if a woman's HIV disease is suppressed or well controlled, the risk for HCV vertical transmission is comparable to that with HCV monoinfection.[22a]

For reasons that are not entirely clear, a significant rate of spontaneous resolution of HCV infection occurs among young children such that up to 50 percent of those with an initial transmission resolve their HCV viremia, leaving a rate of chronic infection after vertical transmission of 3 to 5 percent.[19,113]

Other, less frequent modes of transmission deserve some discussion. Sexual transmission is an inefficient and uncommon route of transmission.[73,86] This has been demonstrated largely in long-term studies of serodiscordant couples, in whom the infection rate was only 1 to 2 percent and many of those who seroconverted had independent risk factors for HCV infection. The exception to this is for men who have sex with men, which is a high-risk exposure.[64] Tattooing is not considered a high-risk exposure, particularly in the current era when sterile techniques are commonplace.[122] This may not be true for a war veteran or prisoner where sterile techniques were not used. Breast-feeding has never been documented as a source of infection and is not contraindicated in new mothers who have HCV infection.[32,62,67] Other microscopic blood exposures from razors and toothbrushes are possible and are targets for prevention measures.[20] In a fraction of patients, no obvious risk factor for HCV exists. It is presumed that some of these microscopic exposures may have been the cause in these cases or that patients may either not recall their high-risk exposure or may not be entirely forthcoming.

CLINICAL MANIFESTATIONS

HCV in most cases is an asymptomatic infection.[4,54] Patients are often diagnosed when seeking medical attention for other reasons and are found to have elevated liver enzymes. In the minority of cases, patients will have acute signs of hepatitis, including malaise, jaundice, abdominal pain, and discomfort.[127] This is often the sign of a robust immune response that may portend clearance of the acute infection. In most patients, there are no acute symptoms and the infection quietly progresses from acute to chronic over the course of several months. The specific determinants of this progression are still largely unknown.

For children infected with HCV, these same observations largely hold true.[54] Infants infected at birth manifest no symptoms for many years.[123] They are often diagnosed only because the mother is known to be infected or has several high-risk factors that warrant screening. Some infants may have elevated transaminases early in life, but most do not. HCV does not alter physical growth or cognitive development. This is an important point to emphasize with parents in counseling during early visits.

Children are also frequently diagnosed during their teenage years during screening for other reasons. Commonly encountered scenarios include testing of those who were preterm infants born in the late 1980s or early 1990s or teenagers who were screened as part of a school blood donation drive and tested positive for HCV antibody.

The major risk for chronic HCV infection is the progression to chronic liver disease, which includes both cirrhosis and subsequent hepatocellular carcinoma (HCC).[111] The rate of these complications in children is low, approximately 5 percent of the time, but it increases with duration of infection. A European study demonstrated that cirrhosis was observed only in children infected for more than 10 years.[53] A large U.S. study demonstrated that many infected children who underwent biopsy had either mild or no fibrosis.[42] Teenagers can have HCV-associated cirrhosis or HCC requiring transplant.[105]

HCV has a variety of extrahepatic manifestations that are primarily observed in adults, but may be possible in children.[17,50] These are skin and joint manifestations such as porphyria cutanea tarda, mixed cryoglobulinemia, and vasculitis that are due to immune complex deposition in small vessels. HCV has also been associated with insulin-resistance and resulting diabetes.[88] Although the specific mechanism of this is unknown, it is likely due to effects of the HCV core protein on regulation of glucose metabolism at multiple levels within liver cells.[87,93] HCV also

has been associated with extreme levels of fatigue and altered mood and concentration.[108] It has recently been demonstrated that HCV can infect brain endothelial cells in vitro, and immunohistochemistry has shown HCV to be present in the brain tissue of chronically infected patients.[34] This raises the possibility that HCV may have some direct effect on the brain.

IMMUNITY

HCV infection is associated with both a cellular and humoral immune response.[16] Responses can be detected after approximately 6 to 8 weeks of infection. Patients with acute infection have evidence of a robust cell-mediated response, with readily detected HCV specific $CD8^+$ T cells.[127] This response mediates clearance of acute infection in these patients. Most patients, however, have specific T cells detected, but the response is weak and ineffective. These patients progress to chronic infection, and over time their T cells display an exhausted phenotype that has little impact on the course of infection.

HCV antibodies are detectable throughout the course of infection, but their role in preventing infection is unclear.[16] As mentioned earlier, neutralizing antibodies to HCV are not observed because of the hypermutation observed in the HCV E2 protein generating many "quasispecies" of HCV that escape neutralization. However, the presence of antibody may alter progression of infection over time in ways not yet understood.

HCV also interacts with the innate immune system to subvert host response to viral infection.[44] Multiple proteins have been demonstrated to directly cleave IFN-induced mediators of host protection.[117] A more specific discussion of these effects can be found in several in depth reviews.[37,44]

DIAGNOSIS

HCV infection can be diagnosed by demonstration of HCV-specific antibody, the presence of HCV RNA from serum or blood samples, or direct demonstration of HCV proteins in serum or blood samples.[57]

First-pass screening of at-risk children is usually done with enzyme-linked immunosorbent assay (ELISA)-based testing. If positive, patients can be tested using a highly specific recombinant immunoblot assay, which detects the presence of antibodies to several HCV proteins. However, this is very rarely necessary. Most practitioners would move immediately to testing for HCV RNA, because the presence of RNA demonstrates chronic infection, which is the most important biomarker of infection. HCV RNA is now done using a real-time polymerase chain reaction (PCR)-based assay that offers the advantages of both reliability for presence of viral RNA and a broad dynamic range for quantitation.[23] If HCV RNA is detected, a frequent next step is determination of HCV genotype, which is done by characterizing the sequence of the HCV polymerase gene.[115] As has been discussed previously, knowledge of genotype can have a major impact on the choice of how and when to treat a patient. An algorithm for the evaluation of a child with HCV-positive antibody testing is outlined in Figure 176-2.

The testing of those infants who are vertically exposed is an altogether different matter. Because of the persistence of maternal antibody and the significant potential for spontaneous resolution of infection in young children, simple ELISA or single-point HCV RNA can be misleading.[20,113] There is no consensus on the best time to test these infants. The approach of this author is outlined in Figure 176-3.

Because no treatment is initiated during infancy, testing is not recommended in the first year. The possible exception to this is if a parent has considerable anxiety over the possibility of infection, performing an HCV RNA test in the first 6 months of life can be considered. If the test is negative, it is very reassuring although not absolute that the child is not infected. A positive result indicates infection but still leaves open the possibility that the infant may spontaneously resolve the infection over the next 1 to 2 years. Preferred timing for testing would be after the first birthday and should include both an HCV antibody and HCV RNA PCR. A repeat result several months later confirming a negative test should be performed before declaring a child uninfected. If the initial test result is positive, a repeat in 6 to 12 months should be performed, and, if the result is still positive, an annual monitoring plan that includes a careful history and physical, liver function testing, and HCV RNA testing should be initiated.

Assessment for Severity of Disease

In addition to a careful physical examination to determine if signs of chronic liver disease are present, assessment of laboratory, radiologic, and pathologic specimens should be performed. The severity of transaminase elevation, if any, should be determined. These tests are notoriously insensitive for disease of mild and moderate severity but are helpful when normal or significantly elevated.[99] Other laboratory tests should be performed to assess the synthetic function of the liver (albumin, prothrombin time, partial thromboplastin time, etc.).[72]

Routine radiologic studies are not necessary for all HCV-infected patients. Ultrasound of the liver can be used at an initial visit for an assessment of any anatomic factors that may complicate future assessments.[72] Unlike hepatitis B virus, with which the risk for HCC is independent of liver damage, with rare exception, HCC with HCV occurs only after cirrhosis is present.[47] If a patient is known to have HCV-induced cirrhosis, annual ultrasounds are justified. If not, periodic testing every 5 years or so may be more appropriate.

Definitive assessment of HCV-induced liver damage is done using a liver biopsy.[72] Certainly all teenagers and adults should have a liver biopsy performed as part of their initial assessment, with the exception of those known to be infected with genotypes that are exceptionally responsive to current standard of care (genotypes 2 or 3). In that case, many providers would proceed to therapy to achieve a definitive cure. In the case of the

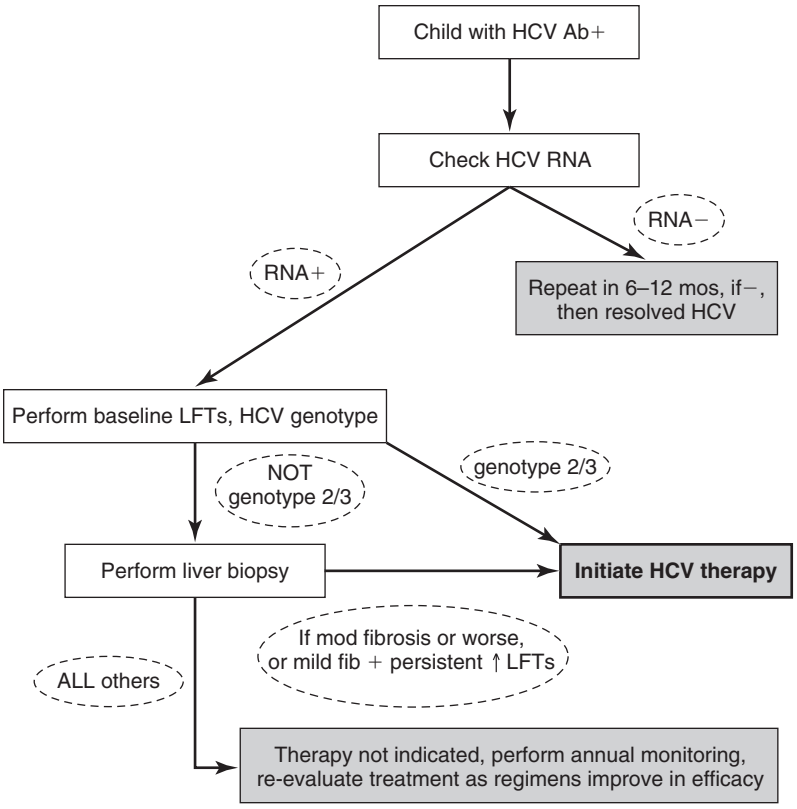

FIGURE 176-2 ■ Suggested algorithm for evaluation of a child with evidence of HCV antibody. End points are highlighted by a *shaded box,* while key result branch points in the decision tree are highlighted in the *ovals* with *dashed borders.*

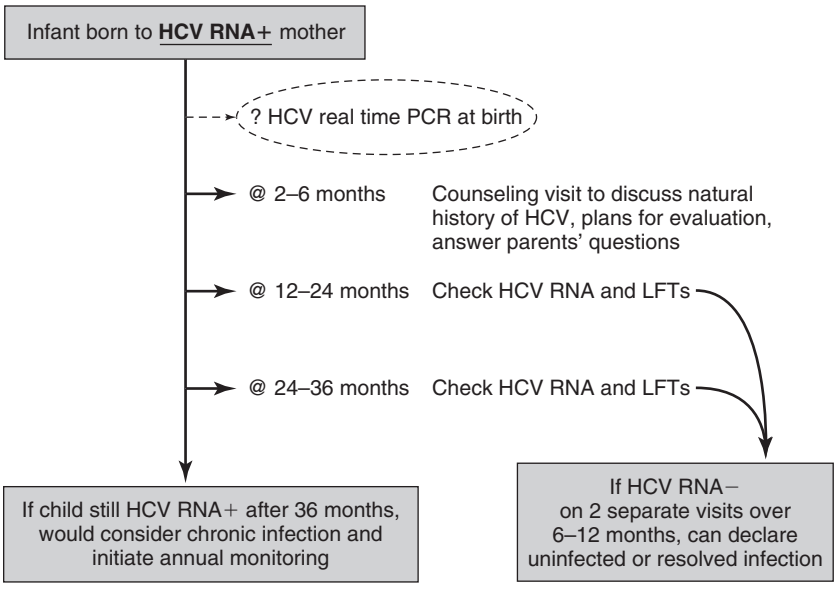

FIGURE 176-3 ■ Suggested algorithm for evaluation of the infant vertically exposed to HCV. End points are highlighted by a *shaded box,* while testing that has not yet been studied are highlighted with *dashed borders.*

child in the first decade of life where rates of significant fibrosis and cirrhosis are exceedingly low, liver biopsy is not necessary, particularly because the timing of potential therapy in these patients has not been determined. It is my opinion that in most cases liver biopsy not be performed until a child is 8 to 10 years of age, unless evidence demonstrates ongoing liver injury (i.e., persistent liver enzyme elevation, complicating risk factors such as obesity, or history of liver disease). However, no consensus exists on this issue.

Many studies have been performed to determine if combinations of laboratory or radiologic tests can be used to assess for liver fibrosis in the absence of a liver biopsy. These so-called noninvasive markers of fibrosis consist of a variety of blood tests that are used to create a score or index that allows for subsequent selection of those more likely to have severe liver damage. Most of these tests perform reasonably well at the ends of the disease severity spectrum, but very poorly in the middle.[90] This is true in children as well.[75] More sensitive ultrasound-based

methods evaluate liver stiffness, which more closely examines for liver fibrosis.[27] These methods are becoming more prevalent in adults and have been piloted in children.[30,91] However, they have not yet supplanted liver biopsy as the primary mode of assessment.

Host Genetics

Studies performed in the last several years have now demonstrated that host genetics play a significant role in the course of HCV disease. As part of a genome-wide associated study, polymorphisms within the *IL28b* gene were initially shown to have an exceedingly high correlation to response to treatment with IFN-based therapy.[40] In examination of the rates of the favorable polymorphisms in different ethnic groups, these polymorphisms potentially accounted for most of the racial and ethnic differences seen using IFN-based therapy. Further studies demonstrated that these polymorphisms also correlated very highly with patients resolving acute HCV in contrast to those whose disease progressed to chronic infection.[119] The mechanism underlying these significant differences has yet to be determined, but because *IL28b* encodes for a lambda-IFN that then regulates subsequent host antiviral responses, studies are being conducted to closely examine the initial lambda-IFN dynamics. No studies have thus far been performed in children, but because these are genetic differences, they likely will have the same impact in children. One study searched for a potential role of this polymorphism in predicting and determining vertical transmission, but no correlation was found.[104] It is important to emphasize that although this polymorphism on a population level is an exceedingly powerful predictor of HCV clearance and response to therapy, it is still unclear how to use this information for the individual patient. The polymorphism is not absolutely predictive of response in either direction; therefore, most practitioners evaluate patients for therapy based on disease status, not factoring in the patient's IL28b status.[26]

TREATMENT

The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition recently issued practice guidelines for the monitoring and treatment of HCV-infected children.[72] The reader is referred there for a detailed discussion of drug doses, adjustments, and side effects.

HCV therapy is undergoing a significant transition as more agents against specific viral proteins emerge from preclinical studies. This section will attempt to cover currently approved information for HCV, as well as what is anticipated in the next several years. Specific attention will be focused on the existing data for treating children. The goal of HCV treatment is the eradication from the bloodstream of viral RNA that persists after the discontinuation of therapy. This is in stark contrast to HIV therapy, which is suppressive only while the medications are continued. It is thought that treatment for HCV reduces the burden of virus in the liver such that either HCV is completely eradicated from the system or the immune system is able to control the virus to such low levels as to be undetectable in the bloodstream. Rare cases have been reported of viral reemergence long after treatment response when immunosuppression is initiated for an unrelated reason, supporting the latter as a likely scenario.[66] For clinical studies, the end point of HCV therapy is the sustained viral response (SVR), which is defined as the absence of detectable HCV RNA at 6 months after the discontinuation of therapy.[36,77] If patients do not achieve SVR, they are categorized as nonresponders (i.e., patients who never suppressed virus during treatment), partial responders (i.e., patients who partially suppressed virus early but then had recrudescence) or relapsers (i.e., patients who completely suppressed virus for some amount of time but then had recrudescence at some point later). Knowledge of this terminology is helpful in interpreting the HCV treatment literature and important because each group has a different prognosis if new treatment regimens are attempted later.

IFN-α and its chemically modified derivatives have long been the backbone for HCV therapy. Old preparations given subcutaneously three times per week offered SVR rates of only 15 to 20 percent.[29] In an attempt to improve the poor pharmacokinetics of traditional IFN, a polyethylene glycol (PEG-IFN) moiety was added to allow for much higher serum concentrations combined with less frequent weekly subcutaneous dosing. The use of PEG-IFN improved SVR rates by almost 20 percent.[36] The mechanism of IFN against HCV is still poorly understood. It most likely acts by an enhancement of host antiviral responses that were otherwise at levels too low to be effective. It is interesting to note that studies examining patients with the favorable and unfavorable IL28b polymorphisms have shown that HCV patients who achieve SVR are those with low levels of IFN-induced gene expression that are readily enhanced with IFN administration, whereas patients who do not respond to treatment have high IFN-induced gene expression that is ineffective in counteracting the virus and incapable of being augmented with exogenous IFN.[2,125] It has long been known that significant racial and ethnic differences exist in rates of response to IFN therapy. African-American and Hispanic/Latino patients achieve SVR at rates significantly lower than those of Caucasian or Asian patients.[78,85] Much of this may be due to differences in IL28b status, but not entirely.

Ribavirin is a current mainstay of HCV therapy. When traditional IFN was still being used with very low SVR rates, other agents were sought to boost its effects. With the addition of orally administered ribavirin, SVR rates increased to almost 40 percent for patients infected with genotypes 1a or 1b.[76] When PEG-IFN was developed, the combination of PEG-IFN and ribavirin resulted in SVR rates of 40 to 50 percent for genotype 1a and 1b patients and 80 to 90 for genotype 2 and 3 patients.[36] The mechanism of action of ribavirin is still unknown but is thought to inhibit viral replication efficiency enough to make the virus more susceptible to other agents. Ribavirin monotherapy has no effect on HCV RNA levels and does not lead to SVR.[14]

PEG-IFN and ribavirin have been studied and approved for use in children at reduced doses.[52,109,110,129] Small pharmacokinetic studies determined that either dosing of PEG-IFN based on weight or body surface area led to serum drug levels comparable to those in adult administration.[110] Ribavirin is given on a weight-based dose for both children and adults.[41] The largest single study of HCV treatment in children was the Pediatric Study of Hepatitis C (PEDS-C) trial, which compared PEG-IFN alone to PEG-IFN plus ribavirin.[109] The rationale for this design was that many thought that PEG-IFN alone may be sufficient in younger children with the absence of many other adverse risk factors. The PEDS-C trial demonstrated that children had overall SVR rates comparable to their adult counterparts (53%) when treated with both drugs, significantly better in contrast to when PEG-IFN was used alone (37%).

Several factors must be considered when treating children with these agents.[72,109] Side effects of PEG-IFN include flulike symptoms and malaise. For children attending school who require maximal function during the school week, PEG-IFN administration on Friday with coadministration of a nonsteroidal anti-inflammatory agent has been effective in alleviating these effects. IFN can also cause neutropenia and hemolytic anemia, both of which can be managed with dose reduction. PEG-IFN has been shown to cause depression and suicidal ideation, dangerous at any age but particularly worrisome during the usually emotionally turbulent adolescent years. A side effect unique to children is the associated arrest of linear growth during PEG-IFN treatment. Although children do experience catch-up growth once the drug is discontinued, long-term follow up is still being conducted to determine whether children actually attain their predicted midparental height.[60]

The issue of when to initiate therapy for a child infected with HCV is still under contention.[72] There is no controversy in the case of a child who has clear evidence of liver compromise from long-standing HCV infection, but these cases are the minority. Because natural history studies of children with HCV do indicate that many of them will do well with only minimal progression of liver fibrosis, treatment initiation remains a controversial issue. Proponents of therapy argue the many potential benefits of treating children: the cost advantage of using less of an expensive drug when treating a smaller person; the number of years of "virus-free" life still ahead for a child; the absence of comorbidities in a child that may complicate treatment; eradicating virus before entering adolescence, when high-risk behavior that can potentially transmit the virus traditionally begins; and for girls, eliminating the potential for vertical transmission. At this point, the decision about when to treat is one that should be individualized on a case-by-case basis.

In May 2011, the first of the HCV-specific antiviral agents were approved. Boceprevir and telaprevir both target the NS3 protease domain of HCV genotype 1a and 1b isolates. When used in combination with PEG-IFN and ribavirin, they are able to boost SVR rates to almost 70 percent in adults.[51,98] These agents also offer an SVR rate of about 70 percent when combined with PEG-IFN and ribavirin for those patients who were relapsers or partial responders to prior IFN-based combination therapy.[10,131] Side effects include a rash that spontaneously resolves in most cases but may require discontinuation in severe cases. They can also cause anemia that can be handled with dose reduction. These agents require a lead in dosing period before initiating PEG-IFN and ribavirin, so their use should be limited to experienced providers. Studies examining the dose and efficacy of these agents in children are currently in the planning and organizational phase.

Several other classes of agents in advanced preclinical development deserve mention. More potent and multigenotype NS3 inhibitors are in phase II and III development.[81] Agents that target the NS5A protein are extremely potent antiviral agents that achieve 3 to 4 log reductions in HCV RNA with single doses.[38,94] HCV NS5B polymerase inhibitors are also in phase II and III development.[132] Studies looking at combinations of multiple agents offer hope of highly potent regimens that offer SVR to the majority of patients. One such pilot study examined adults who were previous nonresponders to PEG-IFN and ribavirin and separated them into two study groups.[71] In one group, 10 patients were retreated with PEG-IFN and ribavirin, along with two orally administered investigational agents, daclatasvir, an anti-NS5A drug, and asunaprevir, a potent NS3 protease inhibitor. In the other group, 11 patients just received the two investigational agents. The results were striking in that 100 percent of patients (10/10) who previously had no response to PEG-IFN achieved SVR when treated with all four drugs. What is also striking is that almost 40 percent of the patients (4/11) given a regimen of just the two investigational agents also achieved SVR. These results affirm the hope of many that HCV therapy will eventually become free of subcutaneous IFN injections and the associated side effects and involve only orally administered, highly potent agents.

What also becomes possible in the future is interruption of vertical transmission using these specific antiviral agents in and around the time of delivery in a manner similar to treatment of HIV.[9] Given the much lower risk for transmission and lower morbidity and mortality in contrast to HIV, further studies into understanding better which mothers transmit HCV and when they transmit the virus would allow more selective drug use.

PREVENTION AND COUNSELING

No specific prevention measures are currently available against HCV infection. Attempts to create a vaccine have been frustrated by the heterogeneity of the virus and an incomplete understanding of how potent cellular responses are generated. Prevention largely rests on avoiding high-risk behaviors, rigorous sterile technique to avoid nosocomial transmission, and screening to identify HCV-infected adults and children so patients can be evaluated and treated. Counsel for the child who is already infected with HCV should include prompt care of bloody injuries, vaccination against other forms of viral hepatitis to avoid potentiated injury to the liver, being

aware of prescription and nonprescription drugs that cause liver toxicity, being aware of the risks of alcohol use when chronically infected with HCV and that no known safe level of alcohol consumption exists for HCV-infected patients.[72] It is also important to reiterate to parents that HCV-infected children grow and develop normally and do not present a risk to classmates. It is also important to advocate for HCV-infected children because some schools and other agencies needlessly continue to try to restrict the attendance and activities of HCV-infected children.

SUMMARY

Children with HCV infection often do very well with few or no long-term effects, but a few children do develop significant liver disease. A working knowledge of how to monitor and manage these patients can assist in mitigating the severity of disease. The treatment of HCV is in the midst of major changes that will revolutionize the field. Although the new anti-HCV agents are still far from being ready to be used for children, familiarity with what will ultimately become available will assist providers in discussions with their patients.

indicate that illness attack rates and hospitalization rates associated with influenza are high in young children. Sporadic infections with novel influenza A viruses of nonhuman origin, usually by avian or swine influenza A viruses, can occur, with highest frequency in children. Uncommonly, the emergence of an influenza pandemic can have profound impact on morbidity and mortality among a wide range of age groups, especially children, throughout the world. Because influenza viruses are dynamic and continually evolving, epidemics are of variable and unpredictable severity, and influenza research is also rapidly evolving, clinicians are referred to sources such as the Centers for Disease Control and Prevention (CDC)* and the World Health Organization (WHO)† for the latest information on influenza surveillance, novel influenza A viruses, and guidance on treatment, prevention, and control of influenza.

HISTORY

Although the authenticity of influenza in medical antiquity is difficult to establish, the disease has existed for more than 2000 years. The epidemic in 412 BCE described by Hippocrates and Livy probably was influenza.[677] Epidemic influenza-like disease occurred in Europe in the 6th and 10th centuries, but the first generally accepted influenza epidemic occurred in December 1173.[292] Hirsch and Creighton[292] noted 299 epidemics of influenza between 1173 and 1875. The first pandemic involving Europe, Asia, and North Africa occurred in 1580, and the first epidemic recorded in the Western Hemisphere occurred in 1647. From 1580 until 1918, at least eight pandemics of influenza occurred.

In more recent times, pandemics of influenza caused by different influenza A subtypes occurred in 1874, 1889, 1900, 1918, 1957, 1968, and 1977. The most noteworthy of all pandemics of influenza occurred in 1918. This event has the dubious distinction of producing the greatest morbidity and mortality rates of all time—more than 40 million deaths occurred in the world.[34,376]

The term *influenza* may have come from the Latin word *influo*, "to flow in," perhaps indicating its airborne transmission. It may be Italian, relating to an "influence," such as the weather or mystical astrologic causes.[376]

VIRUS CHARACTERISTICS

Isolation of influenza viruses from human respiratory tract specimens was first described in 1933.[633] Influenza viruses are negative-sense, single-stranded, segmented RNA viruses encased in a host-derived lipid membrane envelope, belonging to the Orthomyxoviridae family, and are classified antigenically into types, A, B, and C.[537] Morphologically, influenza viruses can have spherical or filamentous shapes (Fig. 177-1). The genome of

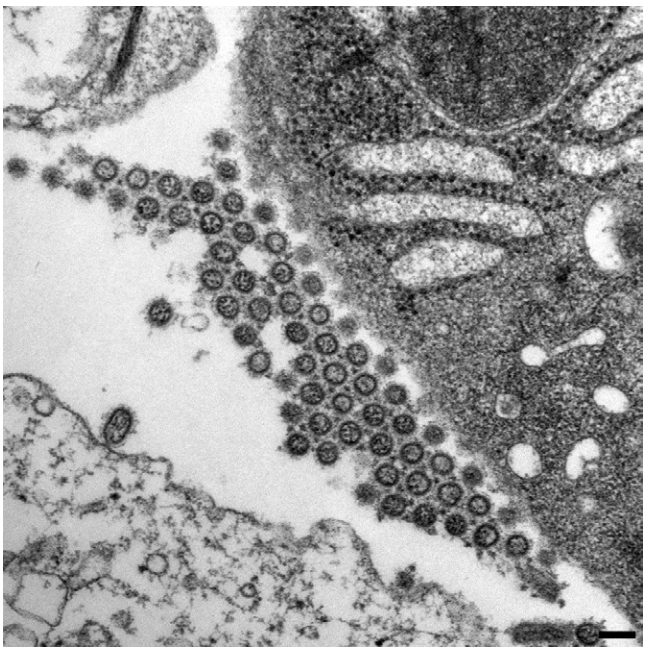

FIGURE 177-1 ■ Influenza A(H1N1)pdm09 viruses budding from infected cells in tissue cell culture. (Electron micrograph provided courtesy Cynthia Goldsmith, CDC. Micron bar indicates 100 nm.)

influenza A and B viruses comprises eight RNA segments, versus seven segments for influenza C virus. The eight gene segments of influenza A viruses range from approximately 850 to 2350 nucleotides, with a total length of approximately 13,500 nucleotides.[297] Influenza A and B viral RNA segments code for up to 12 proteins identified to date, including PB1 (basic polymerase 1; comprises RNA polymerase and associated with endonuclease activity, elongation), PB1-F2 (associated with virulence and proapoptotic activity), PB2 (basic polymerase 2; comprises RNA polymerase, cap recognition), PA (acidic polymerase; comprises RNA polymerase, protease), HA (hemagglutinin), NA (neuraminidase), NP (nucleoprotein; RNA binding, synthesis, nuclear import), M1 (matrix; viral particle assembly), M2 (matrix 2; only found in influenza A viruses; uncoating during virus entry, ion channel function), NS1 (nonstructural; innate immunity, antagonist), and NEP (nuclear export protein, only found in influenza B viruses).[536] A recently discovered influenza A virus protein, PA-X, has multiple functions, including repressing cellular gene expression and modulating the host response (innate immunity) to virus infection.[327]

Influenza viruses have four notable antigens, most importantly the two major surface glycoproteins, hemagglutinin (HA) and neuraminidase (NA), which are spike-like projections from the surface of influenza A and B viruses (Fig. 177-2), whereas influenza C viruses lack neuraminidase.[220] HA is the most important protein because it is the site of attachment to the host cell membrane and therefore is essential in receptor binding affinity, is involved in cell fusion, and is the major influenza virus antigen.[436] Virus strain–specific HA antibodies are induced by infection or vaccination. The NA has an enzymatic catalytic function that results in cleavage of sialic

*Centers for Disease and Control and Prevention: http://www.cdc.gov/flu/professionals/index.htm.

†World Health Organization: http://www.who.int/influenza/en/index.html.

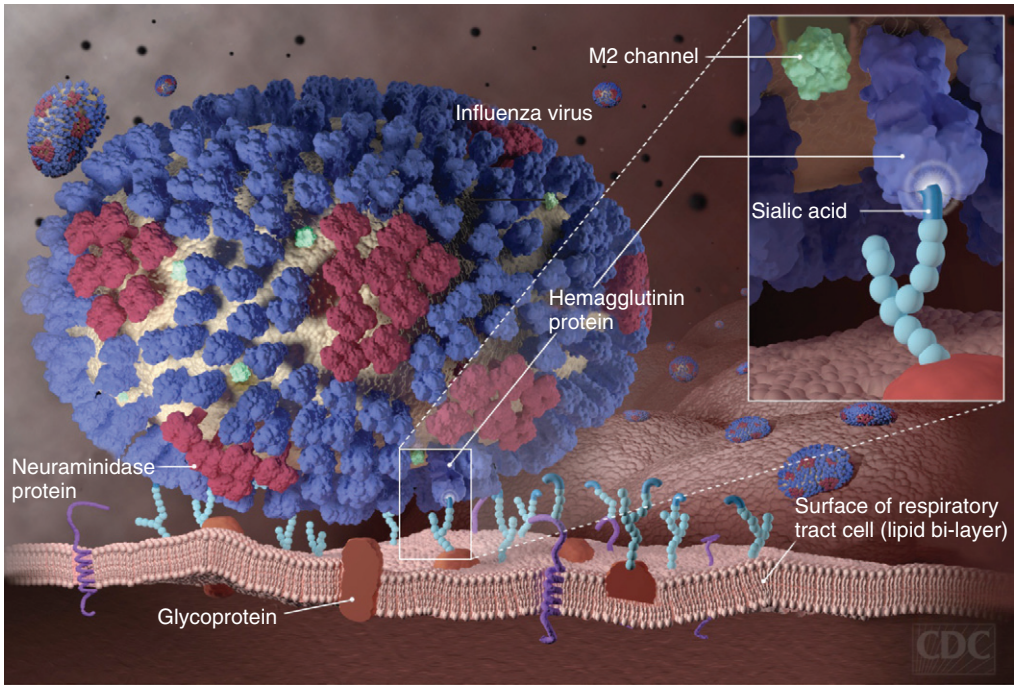

FIGURE 177-2 ■ The two major influenza virus surface proteins, hemagglutinin (HA) and neuraminidase (NA), are shown projecting from the virus surface membrane. HA and NA are also the two main viral antigens. The site of viral HA binding to sialic acid receptors on the surface of the host's epithelial cells is also shown. (See companion Expert Consult website for color version.)

acid receptors from the infected cell, allowing release of infected viral particles (virions). Antibodies to the NA are thought to reduce disease severity, and NA inhibition is the goal of one class of antiviral drugs. Induction of antibodies directed against the matrix proteins is the target of one approach to universal influenza A vaccine development.[200,344] Antibodies targeted at the NP are used in some influenza virus detection assays such as rapid influenza diagnostic tests.

Influenza A and B viruses are most important for public health because of their ability to cause seasonal epidemics. Influenza C virus infections have been described sporadically, usually in children, and because most surveillance systems and clinical laboratories do not conduct influenza C testing, the impact of type C viruses may be underestimated.[84,242,460,461] Influenza A viruses are further classified into subtypes on the basis of antigenic differences in the HA and NA proteins. Designation of influenza A virus subtypes is performed using "H" to denote the HA subtype followed by a specific number for the order first described. Similarly, "N" is used to denote NA subtypes. Sixteen influenza A virus hemagglutinin subtypes have been identified in birds. Based on phylogenetic analyses, the HA subtypes are divided into group 1 (H1, H2, H5, H6, H8, H9, H11, H12, H13, H16) and group 2 (H3, H4, H7, H10, H14, H15), which has implications for development of "universal" influenza vaccines that aim to induce broad heterosubtypic cross immune protection against a range of influenza A viruses subtypes.[120,135,176,177,589] Recently a 17th HA subtype was identified in bats.[682] Nine influenza A virus neuraminidase subtypes have been identified in birds.[736] Phylogenetic analyses divide NA subtypes into group 1 (N1, N4, N5, N8) and group 2 (N2, N3, N6, N7, N9), which has implications for antiviral drug resistance.[391] Group 2 NA subtypes are less likely to develop NAI resistance in contrast to group 1 NA subtypes.[391]

Influenza A viruses are commonly referred to by HA and NA subtype. For example, during 2012 and 2013, two subtypes of influenza A viruses circulated among humans worldwide, A (H3N2), and A (H1N1)pdm09 viruses. The most detailed level of influenza virus classification is by strain based on phylogenetic characteristics, such as the HA nucleotide sequences. Strains are grouped by phylogenetic sequence analysis into clades and genotypes. Nomenclature for human influenza viruses is ordered by virus type, geographic location where the virus was identified, strain number, and year of isolation, with subtype designation for influenza A viruses (e.g., B/Wisconsin/1/2010 and A/Victoria/361/2011 [H3N2]).

Both influenza A and B viruses can undergo random point mutations to the hemagglutinin and neuraminidase genes, with resultant changes to the HA and NA proteins, respectively. These changes are generally gradual, but unpredictable, and may result in minor antigenic changes. Antigenic classification is by relationship to vaccine strains or other reference strains on the basis of ability to cause hemagglutination of red blood cells in a hemagglutination inhibition (HAI) assay using postinfection antisera from infected animals, usually ferrets. For example, a virus strain might be characterized antigenically as similar to a reference virus or vaccine virus strain (e.g., A/Victoria/361/2011 [H3N2]-like) if the cross-reactive HAI titer was within a twofold range. A virus strain with a fourfold or greater difference in cross-reactive HAI

titer using ferret antisera to a reference virus strain is significant and considered antigenically distinct. "Antigenic drift" refers to significant antigenic changes in the HA protein, and to a lesser extent in the NA protein, which are thought to be a major factor in driving seasonal influenza epidemics. Influenza A viruses appear to evolve more rapidly than influenza B viruses, and influenza A (H3N2) viruses have been observed to evolve more rapid antigenic drift than A (H1N1) viruses.[274,588] Reinfection in young children has been observed more frequently with influenza B viruses, even without antigenic drift, than for influenza A viruses.[259] Infection with influenza A and B viruses can occur in the same season, and infection with different influenza A virus subtypes also can occur in the same season.[215] Multiple groups or clades have been identified in the two circulating influenza A virus subtypes (H3N2 and H1N1), whereas only two major antigenically distinct groups or lineages of influenza B viruses have co-circulated (i.e., B/Victoria/2/87-like and B/Yamagata/16/88-like) since 1983.[584]

Influenza A viruses have the propensity to undergo genetic reassortment that can generate new viruses.[274,537] This is believed to occur when an infected animal host (e.g., pig) is coinfected with different influenza A subtype viruses and exchange of RNA virus segments occurs.[74,438] *Antigenic shift* refers to human infection with an influenza A virus of nonhuman origin, which is also referred to as infection with a novel influenza A virus. By definition, this refers to either human infection with a different virus subtype containing a new HA (e.g., H5N1, H7N7, H7N9, H9N2) or infection with a virus with significantly different genetic and antigenic properties (e.g., H3N2 variant virus of swine origin) than viruses of the same HA subtype (e.g., seasonal H3N2 virus) circulating among humans.[631,632] Antigenic shift can result in "dead-end" human infection with no further spread or limited nonsustained human-to-human transmission, or an influenza pandemic can ensue if the virus causes disease, acquires the ability to transmit in a sustained manner, and a high proportion of the global population lacks immunity.[252]

Seasonality

In temperate climate countries, influenza epidemics are associated with relatively cooler temperature periods, such as during fall, winter, and spring. Low influenza activity in temperate countries is generally observed during the summer months, although outbreaks can occur. Various studies have suggested that low relative or absolute humidity and low temperatures are associated with enhanced transmission of influenza viruses, including in animal models.[431,604-606,666] However, exact determinants of influenza seasonality remain unknown. Surveillance data indicate that in subtropical and tropical climates, influenza viruses may be detected year-round, with increases during cooler or rainy periods.[27,380,505,619,719] However, in some areas, increases in influenza activity can occur after the rainy season or in the dry season. Bimodal peaks in influenza activity and associated morbidity and mortality can occur in subtropical countries such as Hong Kong and Singapore, as well as regions of large geographic countries such as southern China.[197,404,749,779] In countries with large areas or with diverse climates, the epidemiology and seasonality of influenza activity may vary widely. One study reported that seasonality of influenza in Brazil was linked to a southbound "wave" of activity from equatorial low-population areas to temperate, more densely populated regions, and suggested that temperature and humidity may be important factors.[10]

Ecology, Hosts, and Infected Animals

The natural reservoir for 16 HA and 9 NA subtypes of influenza A viruses is wild aquatic birds such as geese, ducks, and shorebirds.[736] Genetic reassortment among avian influenza A viruses from different bird species occurs frequently.[251,400,765,772,773] Wild waterfowl can be infected asymptomatically with avian influenza A viruses. Avian influenza A viruses generally infect receptors bearing sialic acids with ∝2,3 galactose linkages ("avian-like receptors"), which are found in the respiratory and gastrointestinal tracts of birds. Avian influenza A viruses are classified as *highly pathogenic* or *low pathogenic* on the basis of molecular and pathogenicity criteria—possession or absence of a highly basic amino acid sequence at the hemagglutinin cleavage site, and mortality in 4-week-old infected chickens.[765] Most avian influenza A viruses are classified as low pathogenic viruses, and only H5 and H7 subtypes have been identified as highly pathogenic avian influenza A viruses; however, most H5 and H7 viruses are low pathogenic. Low-pathogenic avian influenza (LPAI) A viruses generally cause asymptomatic infection in most wild birds, and can cause either asymptomatic infection or mild illness in infected domestic poultry.[206,519,576] Highly pathogenic avian influenza (HPAI) A viruses can cause a spectrum of illness in infected wild birds (asymptomatic infection to rapid death) and domestic poultry (ducks may experience asymptomatic infection more commonly than chickens; rapid spread with high mortality can occur in chickens). Influenza A viruses have been documented to infect a wide range of mammals, including horses, camels, dogs, cats, leopards, cheetahs, tigers, civet cats, and guinea pigs.* Avian influenza A viruses can be transmitted from birds to other animals such as pigs, humans, and marine mammals (e.g., seals and whales). Avian influenza A viruses continue to evolve among birds worldwide.

Swine influenza A virus infections are endemic among pigs worldwide.[74,386,600,721,799] Swine influenza A viruses can bind to receptors bearing sialic acids with ∝2,3 galactose linkages ("avian-like receptors") and ∝2,6 galactose linkages ("human-like receptors"), which are found in the respiratory (primarily ∝2,6 galactose) and gastrointestinal (∝2,3 galactose) tracts of pigs. Because pigs can also be infected with avian and human influenza A viruses, including coinfection with swine influenza A viruses, there is potential for genetic reassortment. Reassortment with other influenza A viruses can occur, including with avian or human viruses, to create new viruses (e.g., triple-reassortant swine influenza A viruses with genes from human, avian, and swine influenza A viruses).[520] These

*References 141, 225, 409, 437, 478, 577, 579, 671, 735, 777.

new viruses can continue to circulate among pigs and may represent a public health threat of zoonotic infection and pose pandemic potential. Thus, pigs have been viewed as "mixing vessels" in which new influenza A viruses can arise, including viruses of pandemic potential.[438,738] A recent example was the emergence of a novel influenza A (H1N1) virus from a swine reservoir to cause the 2009 H1N1 pandemic.[222] Another example is the emergence of a swine influenza A (H3N2) virus with avian, human, and swine influenza A virus gene segments and containing the matrix gene from the 2009 H1N1 virus, in the United States during 2011.[493] This quadruple reassortant virus, referred to as H3N2 variant (H3N2v) virus, acquired the matrix gene through human-to-pig transmission of the 2009 H1N1 virus. Evidence of human-to-swine transmission of the 2009 H1N1 virus to create different reassortant swine influenza A viruses has been documented in pigs in other regions of the world.[191,685,720] Outbreaks of swine influenza A viruses occur seasonally in some countries, but because of poor surveillance, limited data exist on the prevalence and evolution of swine influenza A viruses in pigs worldwide.[632]

Canine influenza A (H3N8) viruses are circulating among dogs and are related to equine influenza A (H3N8) viruses.[18,140] Although equine influenza A (H7N7) viruses have circulated among horses in the past, currently, equine influenza A (H3N8) viruses are circulating among horses.[145,408] Outbreaks of highly pathogenic influenza A (H3N8) viruses among seals have been reported; these viruses are closely related to avian influenza A (H3N8) viruses.[20] Other marine mammals such as whales have been infected with influenza A viruses, but it is unclear whether such viruses continue to circulate among these animals.[291,437,508]

Transmission of human influenza A viruses to other animals without establishing an animal reservoir for these viruses has been documented. Transmission of seasonal or pandemic influenza A viruses to household pets has been reported (e.g., dogs, cats, and cheetah) and to other animals that are raised for consumption (e.g., guinea pigs).[141,146,409,422,465] The host for influenza B viruses is humans, but other animals also can be infected with influenza B viruses (e.g., seals).[527]

Surveillance Among Animals

Surveillance of influenza viruses among animals remains a major gap worldwide. Since 2004, stimulated by concerns of a pandemic arising from an avian reservoir, increased surveillance has yielded data on highly pathogenic avian influenza A (H5N1) viruses and low-pathogenic avian influenza A viruses circulating among domestic poultry and wild birds. A major gap is the lack of monitoring and data for swine influenza A viruses worldwide. The World Organization for Animal Health (OIE) receives reports of outbreaks of animal diseases by member states, including highly pathogenic avian influenza A (H5) and (H7) viruses. Outbreaks of swine influenza A viruses among pigs are not a reportable disease. OIE and the United Nations Food and Agriculture Organization (FAO) global network of expertise on animal influenza (OFFLU) is focused on coordinating, exchanging scientific data and biologic materials (including virus strains), assisting in prevention and control of animal influenza, and collaborating with the WHO Global Influenza Surveillance and Response System on issues at the animal–human interface (http://www.offlu.net/index.php?id=1). OFFLU-participating laboratories include reference laboratories for diagnosis of avian, equine, and swine influenza. Influenza A viruses circulating among animals is the focus of one WHO Collaborating Center for Studies on the Ecology of Influenza in Animals.[754]

Pandemic Influenza Viruses

Influenza pandemics have probably been occurring for millennia.[415] Only influenza A viruses have the ability to cause rare human influenza pandemics. Three conditions are required for an influenza pandemic to occur: the novel influenza A virus must cause disease in humans, have the ability to transmit from person to person in a sustained manner, and a large proportion of the world's population must lack sufficient protective immunity. Pandemic influenza A viruses are thought to emerge through two primary mechanisms: adaptation of an animal influenza A virus that has acquired the ability to infect and transmit among humans (e.g., 1918 H1N1 virus and 2009 H1N1 virus) or through genetic reassortment between a human influenza A virus and an animal influenza A virus (e.g., 1957 H2N2 virus and 1968 H3N2 virus).[495] A theory of recycling of pandemic viruses has been proposed to include H1, H2, and H3 viruses,[801] but the determinants for the emergence of a pandemic virus are unknown.

During the 20th century, three pandemic influenza viruses emerged. The origin of the 1918 H1N1 virus has been debated. Some have argued that the 1918 H1N1 virus was of avian origin, but other researchers believe that a virus of swine origin adapted or acquired the ability for sustained human-to-human transmission.[19,252,566,631,710] The 1957 H2N2 virus was a reassortant virus possessing three RNA segments (HA, NA, PB1) from a low-pathogenic avian influenza A virus and five from H1N1 virus circulating among humans.[252,301,302] Similarly, the 1968 H3N2 virus was a reassortant event between two genes (HA, PB1) from a low-pathogenic avian influenza A virus and six RNA segments from the circulating H2N2 virus.[252,301,302] The 2009 H1N1 ([H1N1]pdm09) virus can be considered a quadruple reassortant virus based on origin from a triple reassortant swine influenza A (H1N1) virus with genes of avian, swine, and human origin (six genes) and a Eurasian swine influenza A (H1N1) virus (NA, M).[222] Before 2009, it was believed that a requirement for a pandemic virus was that it had to possess a different HA subtype than circulating human influenza A viruses. However, the 2009 H1N1 pandemic virus emerged during global circulation of seasonal influenza A (H1N1) virus, but was sufficiently antigenically distinct so that preexisting cross-protective immunity was observed only in elderly persons exposed to the 1918 H1N1 virus or thereafter until significant antigenic drift occurred (e.g., glycosylation of the HA "head" domain) in approximately the late 1920s or early 1930s or in

persons who had received the 1976 swine influenza A (H1N1) vaccine.[265,739,774]

Once a pandemic virus emerges, distinct waves of disease are often observed. The 1918 H1N1 pandemic virus was associated with three "waves" of disease during 1918 through 1920.[477] At some point, a pandemic virus will acquire antigenic changes through antigenic drift and circulate as a seasonal influenza virus. Replacement of a circulating influenza A virus by a pandemic virus has been observed. For example, the 1957 H2N2 virus replaced the H1N1 virus, and the 1968 H3N2 virus replaced the H2N2 virus. An H1N1 virus identical to pre-1957 virus reappeared in circulation in 1977, and is suspected to have had a laboratory source.[363] Some researchers have referred to the reemergence of H1N1 virus in 1977 as the fourth pandemic of the 20th century, whereas others have viewed it as a "pseudo-pandemic." With the emergence of the 2009 H1N1 virus, seasonal influenza A (H1N1) virus has not been detected since 2010. During the first wave of 2009 H1N1 virus circulation, seasonal influenza A and B viruses were rarely detected in many temperate climate countries, although this varied worldwide. Beginning in 2010, the 2009 H1N1 virus co-circulated with seasonal influenza viruses, and in the United States the 2010 to 2011 influenza season had similar proportions of 2009 H1N1, influenza A (H3N2), and influenza B viruses detected.

Virologic Surveillance

In the United States, influenza surveillance comprises multiple components, including virologic and disease-based monitoring.[92] Virologic surveillance is conducted year-round, with respiratory specimens collected from persons with influenza-like illness (temperature ≥38.0° C [≥100.4° F] with either cough or sore throat) tested at public health and private laboratories. Approximately 80 WHO collaborating laboratories, including all state and some local public health and other government laboratories and 60 laboratories participating in the National Respiratory and Enteric Surveillance System (primarily hospital clinical laboratories), submit weekly data on respiratory specimens tested and positive results of influenza testing to the CDC. State public health and other laboratories perform influenza testing using viral culture and molecular assays. All state public health laboratories use the CDC real-time reverse transcription polymerase chain reaction assay (CDC Flu rRT-PCR Dx Panel) that uses primers and probes to detect influenza A, B, H1, H3, H5, influenza A pdm09, and influenza A(H1)pdm09 viral RNA. A subset of influenza viruses that are isolated at WHO collaborating laboratories are sent to the CDC for more detailed characterization, including antigenic characterization, genetic sequencing, phylogenetic analyses, and antiviral susceptibility testing. As part of pandemic preparedness efforts, state public health laboratories submit clinical specimens and extracted RNA from suspected cases of novel influenza A virus infection (human infection with a virus of nonhuman origin, e.g., of avian or swine origin) to CDC for confirmatory testing. This includes specimens testing positive for influenza A viruses that cannot be subtyped by available primers and probes, produce indeterminate results, or are presumptive positive for variant (swine origin) influenza A viruses using the CDC FLU rRT-PCR Dx Panel assay. The CDC issues a weekly influenza surveillance report that is accessible at http://www.cdc.gov/flu/weekly/.

Globally, influenza virologic surveillance is coordinated year-round through the WHO Global Influenza Surveillance and Response System (GISRS). The WHO's influenza surveillance network was established in 1952, and comprises approximately 138 national influenza centers in at least 108 member states, and 6 WHO Collaborating Centers (located in Melbourne, Tokyo, Beijing, London, Atlanta, and Memphis) and 4 WHO Essential Regulatory Laboratories.[752,754] Within a country, influenza surveillance is conducted by one or more national influenza centers, which perform influenza testing, virus typing, and subtyping of influenza A viruses by molecular assays and viral culture.[753] Specimens collected from patients with influenza-like illness at health care facilities participating in sentinel surveillance are submitted to national influenza centers. These national influenza centers send influenza viruses to five WHO Collaborating Center Laboratories for more detailed analyses (i.e., antigenic characterization, genetic sequencing, phylogenetic analyses, and antiviral susceptibility testing). The Influenza Division of the CDC serves as the National Influenza Center for the United States and is a WHO Collaborating Center for the Surveillance, Epidemiology and Control of Influenza. In addition, a network of WHO H5 Reference Laboratories, including WHO Collaborating Centers, was established for laboratory confirmation and detailed analyses of highly pathogenic avian influenza A (H5N1) viruses isolated from human cases.[802] The WHO Collaborating Centers share antigenic and genetic data on influenza viruses identified through surveillance for vaccine strain selection, including seasonal influenza vaccines and prepandemic vaccine candidate development.[17,274]

Currently, influenza A (H3N2), A(H1N1)pdm09 (2009 H1N1 virus), and B virus strains are co-circulating worldwide among humans. Two antigenically distinct lineages of influenza B viruses comprising B/Yamagata and B/Victoria strains continue to co-circulate. Historically, a major gap in influenza surveillance has existed in tropical and subtropical low-resource countries.[226,622] Recently, influenza surveillance was established or expanded using RT-PCR in Asian and African countries, which has contributed to better understanding of the epidemiology of influenza viruses in developing countries[380,505,793] and allowed for detection and monitoring of the spread of 2009 H1N1 virus.[340,360]

Virus Evolution and Spread

Genetic and antigenic evolution of influenza viruses are monitored by various analytical methods. Phylogenetic analyses assess the molecular relationship of strains and classify strain groups into lineages, clades, and subclades. Antigenic analyses assess the antigenic similarity of viruses to reference strains and vaccine strains using antisera, generally from inoculated ferrets, and HAI antibody titers. Antigenic differences resulting in a fourfold or

greater HAI titer from a reference strain are considered significantly different. Recent use of modeling techniques and antigenic cartography techniques to analyze antigenic differences in circulating influenza viruses based on influenza virus surveillance data has provided insight into the evolution and spread of influenza viruses worldwide.[630] One theory, based on data for H3N2 virus strains, suggests that greater evolution occurs in subtropical regions of Southeast Asia ("source"), which then "seed" other regions of the world where less evolution is occurring ("sink"), such as in South America.[116,569,587] Another study suggested that evolution of influenza A (H3N2) viruses during 2003 to 2006 was more complex and that tropical regions of Southeast Asia showed limited genetic diversity and did not maintain a source for seeding seasonal epidemics in temperate climates.[29] This theory proposes that many different localities can be the source of seasonal epidemics in temperate climate countries, with high rates of viral migration occurring between urban centers, based on global travel patterns.[29]

Disease Surveillance

Influenza disease surveillance in the United States comprises multiple components that report data regularly to the CDC.[68,92] Weekly monitoring of the percentage of nonspecific influenza-like illness visits to sentinel primary care providers allows establishment of a seasonal baseline and determination of peaks in influenza-like illness activity, which usually is correlated with peak influenza virus activity. This allows determination of regional and national peaks in influenza-like illness activity. Weekly monitoring of reported deaths from pneumonia and influenza in 122 jurisdictions, comprising approximately one third of the U.S. population, allows comparison to a projected "epidemic threshold" using modeling techniques and to provide a relative assessment of epidemic severity from year to year. During October through May, state and territorial epidemiologists report a weekly qualitative assessment of influenza activity. Hospitalizations for laboratory-confirmed influenza among all ages are monitored through population-based surveillance in the Emerging Infections Program; this allows for determination of rates of laboratory-confirmed influenza hospitalizations by age group.[147,149] Since 2004, pediatric deaths with laboratory testing evidence of influenza virus infection are nationally notifiable to CDC. All of the disease surveillance components are analyzed together with influenza virologic surveillance data to inform an assessment of the impact of influenza in the United States.

Recently, global efforts have been directed to assess the burden of severe influenza disease by conducting syndromic surveillance for severe acute respiratory infection (SARI) requiring hospitalization; when combined with testing of respiratory specimens for influenza viruses, the proportion of SARI cases with influenza can be determined. Use of standard case definitions for SARI allows relative comparisons across countries and regions by season, climate, region, country, age group, and influenza virus.[538,759] When SARI surveillance or influenza virus surveillance is conducted on a population basis (with a defined population denominator), calculation of incidence rates can be determined in outpatients and hospitalized patients to facilitate assessment of the relative severity of influenza seasons.[149,323,558] Health utilization survey data can augment influenza-like illness and SARI surveillance to yield influenza disease burden estimates.[26]

Epidemiology: Seasonal Influenza

In most of the United States, seasonal influenza epidemics occur typically during October to May and peak during January to March, but regional differences may exist in activity, including differences in the predominant circulating influenza viruses.[91] Community influenza activity generally lasts 6 to 8 weeks, but activity may persist longer, especially if antigenically drifted strains emerge. Influenza activity may start earlier and last longer in Alaska and may be detected year-round in Hawaii's tropical climate.[5,273] During the summer months, sporadic influenza outbreaks may occur—for example, in institutions such as long-term care facilities, in summer camps, or among organized tour groups and cruise ship passengers.[94,377,705]

Most people with influenza may not seek medical care, and very few persons with influenza virus infection are tested; thus, the number of symptomatic cases and incidence of influenza virus infection is unknown. It is estimated that an average of 5 to 20 percent of the U.S. population develops influenza illness each year. Community studies of seasonal influenza epidemics have established that the highest infection rates and illness attack rates for laboratory-confirmed influenza or influenza-like illness are typically in young children. Many of these studies were conducted over multiple seasons in the 1970s and 1980s and used different laboratory methods, including serology, to assess influenza virus infection. These community studies have documented high infection and illness attack rates during seasonal influenza epidemics among preschool and school-age children.* Outbreaks of influenza among schoolchildren usually are noted in the early weeks of community influenza activity.[233] Preschool and young school-aged children may introduce influenza to households and are therefore an important group to target for preventing and controlling community influenza activity during seasonal epidemics and pandemics.[28,233,258] During early periods of community influenza activity, absenteeism in schoolchildren peaks, whereas during school holidays, reductions in influenza activity in the community are observed, further suggesting the role of schoolchildren in driving influenza epidemics.[208,235,236,659]

To estimate the national disease burden of influenza, indirect methods such as modeling studies are conducted that use influenza surveillance data and hospitalization discharge or mortality data during periods when influenza virus activity is high (influenza period) in contrast to low (peri-influenza or baseline) periods.† These modeling studies generate excess influenza-attributable hospitalizations or deaths. Some models, including the

*References 28, 208, 210, 233, 423, 473, 659.
†References 97, 324, 672, 674-676, 796.

CDC's projections, incorporate surveillance data for influenza viruses and respiratory syncytial virus. It is estimated that an average of more than 200,000 excess influenza-attributable hospitalizations occur each year in the United States, with the highest rates in persons 65 years of age and older and in young children.[675] Because of the variability of the severity of influenza epidemics, a wide range of mortality estimates has been generated.[97] Estimated hospitalizations and mortality attributable to influenza are highest during seasons predominated by influenza A (H3N2) viruses,[512,674] and seasons predominated by influenza B viruses are generally less severe, although illness attack rates are high among children.[474,512] Approximately 3400 to 49,000 excess influenza-attributable deaths are estimated to occur annually in the United States, with nearly 90 percent of deaths occurring in persons 65 years of age and older.[97] During severe seasons, excess influenza-associated mortality is estimated to exceed the numbers of estimated deaths during the 1968 H3N2 pandemic, likely because of the continued aging of the U.S. population. Although mortality during influenza pandemics attracts heightened attention, some seasonal influenza epidemics result in higher numbers of deaths, and because pandemic influenza A viruses undergo antigenic drift to circulate as seasonal influenza A viruses for many years, the cumulative mortality of seasonal influenza epidemics can exceed all but the most severe influenza pandemics.

High-Risk Pediatric Groups

Population-based studies indicate high rates of outpatient and emergency department visits for influenza in children in the United States.[67,498,500,516,558] Retrospective studies using seasonal influenza surveillance data estimate that the highest hospitalization rates among children in the United States are in those younger than 5 years of age; rates are higher in infants younger than 2 years in contrast to those 24 to 59 months and highest in those younger than 12 months, with high hospitalization rates in those with chronic medical conditions.* Direct methods using laboratory-confirmed influenza data to determine seasonal influenza incidence and population-based studies of laboratory-confirmed influenza hospitalizations in the United States further indicate that the highest hospitalization rates among children are in those younger than 2 years of age (highest rates in infants younger than 6 months), followed by those 24 to 59 months of age,† and that a high proportion of hospitalized influenza patients have chronic medical conditions. Using laboratory-confirmed influenza hospitalizations may underestimate the burden of influenza because of testing biases and limitations of rapid influenza diagnostic tests.[247]

Overall, these disease burden studies and surveillance data indicate that children at highest risk for influenza complications are those younger than 5 years of age, particularly those younger than 2 years, with the risk increasing by decreasing age.[567] Additionally, children with certain underlying medical conditions are considered at highest risk for influenza complications because of exacerbation of chronic disease or severe respiratory illness, including those with chronic pulmonary disease (e.g., asthma or cystic fibrosis); cardiac disease (e.g., congenital cardiac disease, congestive heart failure, or coronary artery disease); metabolic disorders (e.g., diabetes mellitus, inherited metabolic disorders, or mitochondrial disorders); hematologic disease (e.g., sickle cell anemia); renal disease; hepatic disease; immunosuppression; neurologic and neurodevelopmental conditions (including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy [seizure disorders], stroke, intellectual disability (mental retardation), moderate to severe developmental delay, muscular dystrophy, or spinal cord injury); children receiving chronic aspirin therapy; morbid obesity; and persons who are American Indian or Alaska Natives.[111,499]

Economic Impact

The economic impact of influenza in children includes the direct medical care costs of illness (for medications, tests, a clinic or emergency department visit, health care provider consultation fees, or hospitalization costs), out-of-pocket costs (for over the counter medications or travel costs to medical care), as well as possible associated indirect costs, such as work time loss for a parent or guardian to care for a sick child.* Measuring the economic impact depends on whether the societal or individual perspective is assessed and may vary by whether assessments are conducted in developed countries versus middle-income or low-resource settings, different climates, health care–seeking behavior, and the structure of the health care system (e.g., national health insurance vs. private insurance). Overall, the direct medical costs, out-of-pocket costs, and indirect costs of seasonal influenza in young children are substantial, even for outpatient and emergency department care.[524] One study estimated that the total burden of seasonal influenza epidemics in the United States was $87 billion.[472]

Global Disease Burden

Outside of developed countries, the burden of influenza is less well understood, but recent studies indicate that influenza is a major public health problem in temperate, subtropical, and tropical regions.[226,622] Influenza virus infections occur worldwide in children, resulting in medically attended outpatient visits, although the burden may be underestimated by surveillance data because many ill persons may not seek medical care.[226,416,622] Therefore, household population–based surveillance may be more informative about influenza disease burden, especially in developing countries.[77,572] Use of serosurveys in community-based studies can further enhance determination of the burden of influenza virus infection in developing countries.[299] Such studies consistently show a high burden of influenza in school-aged children. Data from

*References 324, 485, 498, 516, 674, 796.
†References 15, 149, 150, 427, 485, 500, 558, 599.

*References 124, 184, 189, 357, 472, 524.

other countries consistently indicate that young children are hospitalized with complications of influenza more frequently than older children.[167,350,441,619,787] Influenza viruses can be detected in respiratory specimens from young children with acute lower respiratory tract disease worldwide.* Syndromic surveillance for severe acute respiratory infection (SARI) indicate that influenza virus infection causes SARI in young children in many diverse settings.[26,33,195,196] One study reported a high incidence of influenza virus infection in infants younger than 6 months of age.[285] A review of studies from sub-Saharan Africa reported that among children hospitalized for acute respiratory tract infections, a median of 6.3 person were associated with influenza.[226] One study estimated that during 2008, 90 million new cases of influenza occurred among children younger than 5 years of age, resulting in 20 million cases of acute lower respiratory tract infection (ALRI) and 1 million cases of severe ALRI.[492]

Influenza-Associated Mortality

Death is an uncommon outcome of influenza virus infection, but data on pediatric mortality associated with seasonal influenza are limited. One modeling study estimated that 38 to 92 pneumonia or respiratory and circulatory deaths attributable to influenza in children younger than 5 years of age occurred each year in the United States.[674] During 2003 and 2004, a severe influenza A (H3N2) virus season, 153 deaths in children with laboratory evidence of influenza virus infection were reported to CDC through enhanced passive surveillance.[56] Pediatric influenza-associated deaths were also noted during the 2003 and 2004 season in the United Kingdom.[336] Pediatric influenza-associated deaths became a nationally notifiable condition in the United States during 2004, and from 2004 to 2008, a range of 46 to 88 deaths were reported to CDC.[201,546] These data indicate that influenza virus infection causes the highest number of pediatric deaths of any vaccine-preventable disease in the United States. A high proportion of deaths occurred in children with underlying chronic comorbidities, most deaths occurred in children who were not vaccinated, and a substantial proportion died at home or in an emergency department with a short median time from illness onset to death. This suggests that some deaths have occurred unexpectedly, after a fulminant progression that followed an initially mild illness, as a result of influenza virus infection alone or with secondary invasive bacterial coinfection.[56,201] Although the median age has been increasing in recent years, one study reported that the highest mortality rate was in children younger than 6 months of age.[56] Since the 2009 H1N1 pandemic, the number of pediatric seasonal influenza-associated deaths has ranged from 34 to 122 per year.[93] Deaths have been associated with complications of influenza A or influenza B virus infections and are reflective of the circulating influenza virus strains. It is likely that reported deaths are an underestimate of all pediatric influenza-associated deaths in the United States, because some deaths related to influenza virus infection are not suspected or tested for influenza or may not yield evidence of influenza virus infection when tested. One study estimated that during 2008, a range of 28,000 to 111,500 influenza-attributable ALRI deaths occurred worldwide among children younger than 5 years of age.[492]

Zoonotic Influenza

Sporadic human infections with influenza A viruses of nonhuman origin have been identified and usually are associated with recent direct or close exposure to animals such as poultry or pigs that are infected with influenza A viruses. A human case of conjunctivitis with H7N7 virus from a seal was reported in a marine mammal worker.[737] Human infections with influenza A viruses from animals are referred to as cases of novel influenza A virus infection. Novel influenza A virus infection represents antigenic shift and is an event of public health importance because of the pandemic potential, but does not necessarily result in an influenza pandemic unless sustained human-to-human transmission occurs. The frequency and incidence of novel influenza A virus infections is unknown in the United States and worldwide because of surveillance and testing limitations. Although novel influenza A virus infections in the United States have been a nationally notifiable condition since 2007, the reported number of cases is likely a large underestimate of all cases that have occurred, because most such novel influenza A virus infections do not result in severe disease, few cases may be suspected or tested, and testing may not detect or specifically identify a suspect novel influenza A virus infection unless detailed molecular testing using specific primers and probes, viral culture, or genetic sequencing is performed. For example, antigen detection tests (e.g., rapid influenza diagnostic tests and immunofluorescence) do not distinguish between human infection with seasonal influenza A viruses and animal influenza A viruses.

Avian Influenza A Virus Infections

Human infections with different avian influenza A virus subtypes resulting in respiratory illness have been identified to date, including low-pathogenic avian influenza (LPAI)A (H7N2, H7N3, H7N7, H7N9, H9N2, and H10N7)[23,387,411,529,548,628] and highly pathogenic avian influenza (HPAI) A (H5N1, H7N3, and H7N7) viruses.[1,109,378,694] Whereas many avian influenza A virus infections identified to date have been in adults, most of the LPAI H9N2 virus infections identified to date have been in children.[122,548] LPAI virus infections generally have resulted in uncomplicated influenza illness with fever, myalgia, and upper respiratory tract symptoms (i.e., nonproductive cough, sore throat, rhinorrhea, nasal and congestion). Some children with LPAI H9N2 virus infections have been hospitalized with uncomplicated influenza, with full recovery.[702] Both LPAI and HPAI H7 virus infections can cause conjunctivitis with or without upper respiratory tract symptoms, and H7 viruses have been shown to cause ocular tropism.[42] Sporadic cases of lower respiratory tract disease with LPAI H7N2, H7N3, or H9N2 virus infection have been reported in adults,

including in immunosuppressed persons.[122,628] Although most cases of LPAI virus infection are associated with recent direct or close exposure to poultry, in some cases the exposure was not determined. However, LPAI viruses circulate widely among wild birds and domestic poultry and are likely the source of transmission. No human-to-human transmission of LPAI viruses has been reported, but limited human-to-human transmission should be considered in cases without identified direct or indirect poultry exposure. In the United States only a few cases of LPAI H7N2 virus infection have been reported.[529]

A wide spectrum of illness has been reported with HPAI virus infections, including conjunctivitis alone with HPAI H7N3 or H7N7 virus infection and relatively mild uncomplicated febrile upper respiratory tract symptoms with or without conjunctivitis (HPAI H7N7 virus).[109,378,694] During the spring of 2003, a large outbreak of HPAI H7N7 virus among domestic poultry occurred at farms in the Netherlands.[378] This outbreak was associated with one human fatal adult case with acute respiratory distress syndrome (ARDS) in a veterinarian and other cases of conjunctivitis with or without uncomplicated influenza illness.[207,378] Limited human-to-human transmission of HPAI H7N7 virus was documented in some households.[378] Limited, nonsustained HPAI H5N1 virus infections have caused both clinically mild and critical to fatal illness.[1]

The first human case of poultry-to-human transmission of HPAI H5N1 virus was identified in a child in Hong Kong during 1997.[650] Eighteen human cases of HPAI H5N1 virus infection were identified during May to December 1997, with 6 deaths.[117] The spectrum of disease in 11 pediatric patients included uncomplicated influenza illness, ARDS, and multiorgan failure. Additional H5N1 cases were identified in early 2003.[547] Since November 2003, more than 600 human cases of HPAI H5N1 virus infection with approximately 60 percent case-fatality proportion have been reported from 15 countries to the WHO.[751] These cases are associated with the ongoing epizootic of HPAI H5N1 viruses among poultry. Currently, the United Nations Food and Agricultural Organization (FAO) considers six countries endemic for HPAI H5N1 virus among poultry, and outbreaks have occurred among nearby nonendemic countries.[697] HPAI H5N1 viruses continue to evolve among poultry and some wild birds and have been diversifying into distinct clades (groups), subclades, and genotypes worldwide.[757,758] To date, human infections have been documented with clade 0, 1, 2, and 7 viruses, including subclades 2.1, 2.2, and 2.3 viruses.[1] In 2012, HPAI H5N1 viruses transmitting to humans included clade 1.1, 2.2.1, 2.3.2.1, and 2.3.4.1 viruses. HPAI H5N1 viruses generally bind to receptors bearing sialic acids with ∝2,3 galactose linkages, usually found in the lower respiratory tract (type II pneumocytes).[457,458,613] However, HPAI H5N1 viruses have been shown to bind to tissues (in ex vivo culture) found in the upper respiratory tract, including tissues without known receptors.[507] HPAI H5N1 viruses have also been found to infect the gastrointestinal tract, brain, placental tissue, and fetal lung cells.[1] Both upper and lower respiratory tract infections with HPAI H5N1 viruses have been identified in pediatric patients.

Risk factors for HPAI H5N1 virus infection include recent direct or close contact with sick or dead poultry or visiting a live poultry market, although in some cases, the source of infection was not determined.[1,601,798] Sporadic clusters of human HPAI H5N1 cases have been identified in some countries. Nearly all clusters have occurred among blood-related family members.[300,342] In most clusters, a common poultry exposure was the likely source of infection, but some cases of limited, nonsustained human-to-human transmission following close, prolonged unprotected exposure to a symptomatic HPAI H5N1 patient, including nosocomial transmission, have been reported.[342,696,726] For HPAI H5N1 virus and other avian influenza A viruses to transmit efficiently among humans, it is believed that adaption in receptor-binding affinity to human influenza A virus receptors is needed.[314] Two recent studies suggest that only a small number of viral mutations are needed for HPAI H5N1 viruses currently circulating among poultry to transmit well in a mammalian (ferret) model.[286,315,586]

Although most adult HPAI H5N1 patients have experienced severe or fatal disease, clinically mild illnesses have been identified in young children, including some patients identified through routine surveillance for influenza-like illness.[76,316,522] In addition to febrile upper respiratory tract illness and viral pneumonia, some HPAI H5N1 patients have had vomiting and diarrhea. Early clinical presentation includes febrile respiratory or gastrointestinal illness, and such patients have been diagnosed with more common diseases (e.g., dengue or typhoid), even in endemic countries.[1] Atypical cases in children have presented with encephalitis or gastroenteritis preceding viral pneumonia.[21,154] Eliciting a history of recent exposure to sick or dead poultry and clinical suspicion may facilitate diagnosis in endemic countries. Findings in some HPAI H5N1 patients at hospital admission include leukopenia, lymphopenia, moderate thrombocytopenia, bilateral pneumonia, dyspnea, tachypnea, and hypoxia.[701] Diagnosis is by testing respiratory specimens with RT-PCR using H5-specific primers and probes. Early clinical presentation and early initiation of antiviral treatment with the neuraminidase inhibitor oseltamivir is associated with survival in pediatric HPAI H5N1 virus infection in retrospective cohort studies.[3,522,701] Clinical management includes early NA inhibitor treatment, supportive management of complications (i.e., shock, viral sepsis, respiratory failure, ARDS, and renal failure), and adherence to recommended infection control measures (i.e., standard, droplet, and contact precautions; eye protection; and respiratory protection with N95 or equivalent respirators if available or surgical masks).[3,701,741] Few cases have been identified with secondary invasive bacterial coinfection, although nosocomial infection has been reported.[36,696,726]

Swine Influenza A Virus Infections

Human infection with swine influenza A viruses is referred to as variant virus infection and designated with a "v" following the subtype identification (e.g., H3N2v virus infection). Swine influenza A viruses are endemic among pigs in the United States and worldwide, and

sporadic transmission to humans has been identified, especially in the United States since novel influenza A virus infections were made a nationally notifiable condition in 2007.[148,490,504,611,670] However, because surveillance for swine influenza A viruses among pigs is poor and limited, understanding of the evolution of swine influenza A viruses and the public health risk is unknown. Undoubtedly, variant virus infections are underestimated, because most human infections do not result in severe illness and influenza testing is not performed. Most cases of variant virus infection have occurred after recent direct or close exposure to pigs. Examples of variant virus infections with different influenza A virus subtypes have been identified, including with classic H1N1, triple-reassortant H1N2, triple-reassortant H3N2, and triple-reassortant H3N2 virus with the M gene from influenza A(H1N1) pdm09 virus.[110] The majority of variant virus infections have occurred among children. The clinical spectrum of variant virus infection ranges from uncomplicated influenza (e.g., febrile upper respiratory tract illness) to exacerbation of underlying chronic disease (e.g., asthma), to severe and fatal illness. Most hospitalized patients have been at increased risk for influenza complications because of age or underlying comorbidities.[104] Most variant virus patients have experienced self-limited influenza illness with full recovery. Some patients have experienced vomiting and diarrhea. In 1976, human infections with a novel swine influenza A (H1N1) virus (A/New Jersey/76 [Hsw1N1]) caused severe respiratory illness in 13 military trainees, with 1 death at Fort Dix, New Jersey.[224] Because A/New Jersey/76 virus was similar to the 1918 H1N1 pandemic virus, and human-to-human transmission had been observed at Ft. Dix, a large vaccination program was implemented.[602] However, no influenza pandemic occurred and an increase in cases of Guillain-Barré syndrome (GBS) was found in vaccinees.[454,602]

Before 2011, variant virus infections were sporadically identified in the United States, with 12 cases identified in 2011. However, beginning in July 2012, cases of human infection with an H3N2v virus containing the M gene from influenza A(H1N1)pdm09 virus were increasingly identified in the United States.[102,110] As of September 2012, more than 300 confirmed H3N2v patients had been identified, with 16 hospitalizations and 1 death.[104] Of 11 hospitalized H3N2v patients, 10 were in children, with a median age of 6 years, most hospitalizations were brief, and only 1 case was severe. Of the 11 hospitalized H3N2v patients, 6 were persons at high risk for complications because of age younger than 5 years or underlying chronic comorbidities.[105] It is possible that acquisition of the M gene from the influenza A(H1N1) pdm09 virus may facilitate increased transmission among pigs, from pigs to humans, and among humans. Most H3N2v cases were identified in children who raised and exhibited pigs at agricultural fairs, especially in 2012, because H3N2 viruses circulated more widely among pigs in the United States[102,110] Some cases were identified among visitors who entered a swine barn at an agricultural fair. Limited, nonsustained human-to-human transmission of H3N2v viruses has been reported in persons without swine exposure, including young children at a child care center. Limited serologic data suggest that children lack immunity to H3N2v virus infections and may be at greater risk for infection after exposure to infected pigs than older adults.[101,627,722]

No commercially available tests can specifically identify variant virus infection. Clinical suspicion depends on eliciting a history of recent direct or indirect contact with pigs or with an ill person who had recent swine exposure. In suspected cases, respiratory tract specimens should be collected for testing at a state health department laboratory using the CDC FLU rRT-PCR Dx Panel assay, which can identify presumptive probable H3N2v virus infection, which is classified as a confirmed H3N2v case.[102] Further testing, sequencing, and viral characterization are performed at the CDC. Empirical NA inhibitor antiviral treatment is recommended to be started as soon as possible for any hospitalized patients, those with severe or progressive disease, or outpatients at increased risk for influenza complications if H3N2v virus infection is suspected.[104] Early antiviral treatment (within 48 hours of illness onset) of non–high-risk patients is encouraged.[104] For hospitalized patients, infection control precautions such as for seasonal influenza should be followed. In addition to H3N2v cases, other human infections with variant influenza A viruses containing the M gene from the 2009 H1N1 virus were identified in the United States during 2012, including H1N1v and H1N2v viruses.[113]

Pandemic Influenza

The epidemiology of pandemic influenza is different from that for seasonal influenza because many people, especially children and young adults, lack immunity to a pandemic influenza A virus, whereas older adults may have some cross-reactive antibodies from prior infection with antigenically similar influenza A viruses. Although the severity of influenza pandemics is variable, illness attack rates are highest among children and among household members, although hospitalization rates and mortality rates may be higher in adults.[35] Substantial outbreaks of pandemic influenza typically occur among schoolchildren.[406] Pregnant women are also disproportionately affected during influenza pandemics in terms of severe disease and mortality in contrast to nonpregnant women.[169,623] In contrast to seasonal influenza epidemics, in which mortality is highest among elderly persons, during influenza pandemics, an age shift toward deaths occurring in persons younger than 65 years of age is often observed.

The 1918 H1N1 pandemic was the most severe pandemic of the 20th and 21st centuries to date, with estimates of a case-fatality proportion of 2 percent, 600,000 deaths in the United States, and 50 to 100 million deaths worldwide.[363,477,668,733] This pandemic has been called "Spanish influenza," but did not begin in Spain. Although some think this pandemic started in China, some epidemiologic evidence suggests that it may have had an impact in the United States first in the spring of 1918. Severity was higher in the second wave of the 1918 H1N1 pandemic than in the first wave. Mortality rates were high in young children, the elderly, and persons between 15 and 35 years of age, resulting in the "W"-shaped mortality curve.[217,363,477,668,733] The 1918 H1N1 virus caused rapid

progression to pneumonia, and it has been proposed that secondary invasive bacterial coinfection in the preantibiotic era contributed to the high mortality, but this is based on only very limited autopsy tissue data.[479,480,607] Studies of the 1918 H1N1 virus in experimentally infected animals and molecular studies indicate that this virus possessed molecular markers associated with severe virulence and caused severe lung pathologic conditions with viral-induced and inflammatory damage.[347,541,692] The 1957 H2N2 virus caused a relatively moderately severe pandemic, with an estimated 70,000 excess deaths in the United States.[512] Viral pneumonia also was observed in children and nonelderly adults during the 1957 H2N2 pandemic.[430] The 1957 H2N2 pandemic is referred to as *Asian influenza* and may have originated in China.[363] The 1968 H3N2 virus caused a relatively mild pandemic that is referred to as *Hong Kong influenza*, with an estimated 34,000 excess U.S. deaths.[363,512] The 1968 H3N2 pandemic was the first pandemic with some availability of antiviral agents for treatment (amantadine). Regional differences in impact of the 1968 H3N2 pandemic have been reported, with Asia and the Americas being affected before sub-Saharan Africa.[803]

In 2009, a novel influenza A (H1N1) virus of swine origin emerged and caused the first influenza pandemic of the 21st century.[152] Epidemiologic evidence suggests that southeastern Mexico may have been affected first, with wider spread in Mexico and to the United States and Canada before spreading among humans worldwide.[35] The epidemiology of 2009 H1N1 indicated a younger age shift in contrast to seasonal influenza epidemics with higher hospitalization rates in school-aged children and young adults.[707] Hospitalization rates were highest in infants and young children, whereas mortality rates were highest in persons 50 years of age and older and the elderly. Hospitalization rates were substantially higher for 2009 H1N1 among children 5 to 17 years of age and adults 18 to 49 years in contrast to seasonal influenza.[139] Among hospitalized patients, a higher proportion of adults had underlying medical conditions than children. In some patients, more commonly in adults, a rapidly progressive viral pneumonia led to respiratory failure, ARDS, and refractory hypoxemia and was sometimes accompanied by vasopressor-dependent shock and multiorgan failure.[35] Autopsy tissue studies indicated that 2009 H1N1 virus can bind to receptors such as type II pneumocytes deep in the lower respiratory tract, and that up to 30 percent of fatal cases had evidence of bacterial pneumonia *(Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes)*.[610]

2009 H1N1 was the first pandemic in which antiviral drugs, primarily oseltamivir, were widely available in many countries, although not in low-resource settings. One study estimated that antivirals may have prevented 8400 to 12,600 hospitalizations, mainly in adults, in the United States.[25] Mortality was low in Japan, where early antiviral treatment was implemented widely.[656] In the United States, more than 300 children (median age, 9.4 years, many with underlying medical conditions) died of complications related to 2009 H1N1 virus infection.[138] Children in the United Kingdom who died of 2009 H1N1-related complications before hospital admission were more likely to have been previously healthy or have mild preexisting disorders in contrast to children who died after hospital admission.[590] Risk factors for severe disease included the same high-risk groups for seasonal influenza complications. As in previous pandemics, indigenous persons, such as aboriginal people, First Nations Canadians, American Indians, and Native Alaskans experienced high attack rates. Notably, obesity, particularly morbid obesity, was associated with critical illness and death worldwide.[707] One study estimated that approximately 200,000 respiratory deaths and an additional 83,000 cardiovascular deaths occurred worldwide, with 80 percent occurring in persons younger than 65 years, during the 2009 H1N1 pandemic.[151] In the United States, monovalent 2009 H1N1 vaccine did not become available until after the fall second wave had peaked but was still cost-effective in children.[563]

Transmission and Viral Shedding

Influenza viruses (seasonal and pandemic influenza viruses) are believed to be transmitted among humans primarily through large droplets and small particle droplet nuclei (aerosols) that are expelled by a symptomatic person with influenza virus infection to susceptible persons in close proximity (~1 to 2 meters).[69,70,669] Generally, large and small droplets are not observed to spread for longer distances because of desiccation and drop off. Although influenza viral RNA has been detected in exhaled breath, it is uncertain whether this can lead to transmission at very close distances.[188] Some studies have reported transmission of influenza viruses aboard planes.[30,523] The influence of air currents (i.e., ventilation, fans, and ventilators) in closed spaces is unknown. One study of nosocomial influenza virus transmission on two adjacent open general medical wards found an association with noninvasive ventilation in the index patient and an air jet from an air purifier, suggesting the role of aerosols.[748] Contact transmission is believed to be possible, but the relative contribution to influenza virus transmission is unknown. Experimental human challenge studies may provide insight on the relative contribution of influenza virus transmission modalities.[364,365] Influenza viruses can persist on nonporous surfaces, and influenza viral RNA was detected on the fingertips of children in one household study.[70,620] A randomized controlled trial (RCT) of hand washing with soap and water in Egyptian schoolchildren found significant reduction in rapid influenza test–confirmed influenza cases.[661] One U.S. RCT of hand sanitizer use and cough hygiene in schoolchildren reported a reduction of influenza A but not influenza B illness.[641] Other studies in schoolchildren or households have suggested a reduction in acute respiratory tract infection, influenza-like illness, and laboratory-confirmed influenza by hand washing during the influenza season.[394,432]

Data from animal models suggests the role of viral factors in influencing influenza virus transmission.[41] Single or two mutations in the HA gene can change or enhance pandemic influenza A virus receptor binding affinity and transmissibility in the ferret model.[330,693] One study suggested that the NA influenced increased

transmissibility of the 2009 H1N1 virus in the ferret model in contrast to closely related swine influenza A viruses with a different NA.[784] Switching the receptor binding affinity from avian-like to human-like in ferrets experimentally infected with mutated HPAI H5N1 virus did not enhance transmissibility, suggesting that other viral factors play a role in transmissibility.[443]

In household studies, the serial interval (time from illness onset of an index case to onset of a secondary case) is approximately 3 days.[395] This correlates with influenza viral load in the upper respiratory tract, which peaks during the first 2 days after illness onset and decreases substantially by about 4 to 5 days after illness onset.[410] The incubation period for influenza virus infection ranges from 1 to 4 days and is typically 1.5 days.[405] Influenza viruses can be detected the day before illness onset. Rare cases of a longer incubation period in which influenza virus was isolated up to 6 days before illness onset in young children have been reported.[215] It is unlikely that asymptomatically infected persons transmit influenza viruses to close contacts, and asymptomatic infection is not believed to contribute to community transmission, although transmission during the incubation period before illness onset has been reported.[250] Asymptomatic infection is important for ascertaining the denominator of all infected persons among those exposed in household and community studies.[211,326,545] Older studies that used serology suggest seasonal influenza virus infection attack rates of 17 to 46 percent in familes.[209,334,659]

In infants and young children, influenza viral replication may be detected for 7 to 10 days and up to 21 days.[250,256] School-aged children may have viable influenza virus detected for approximately 5 days after illness onset. Molecular assays can detect influenza viral RNA for longer periods, but this may not necessarily represent viable virus. Higher influenza viral load is correlated with longer viral shedding.[410] Children who are immunocompromised or immunosuppressed (especially severely immunosuppressed) may have detectable influenza viral replication for weeks to months.[223,375,581] Although it is generally believed that young children can have high levels of influenza viruses in the upper respiratory tract and shed influenza viruses for longer periods than adults, some studies have found no differences in viral load levels in children versus adults.[266,421] Hospitalized patients with pneumonia and respiratory failure can experience prolonged viral replication in the lower respiratory tract, although most data are from critically ill adults.[35,63,410,574]

PATHOGENESIS AND PATHOLOGY

A combination of many viral and host immune and host genetic factors affects the pathogenesis of influenza virus infection. The application of reverse genetics methodology to influenza virus research has facilitated understanding of viral molecular factors associated with pathogenesis.[205,494,496] The receptor binding affinity of influenza viruses is an important determinant of the host species range and may also influence disease severity. Human seasonal A and B and pandemic influenza A viruses bind preferentially to receptors on upper respiratory tract epithelial cells bearing a terminal sialic acid linked to galactose by an ∝2,6 linkage ("human-like" receptor binding affinity).[775] In contrast, influenza viruses that bind primarily to receptors on lower respiratory tract epithelial cells bearing a terminal sialic acid linked to galactose by an ∝2,3 linkage ("avian-like" receptor binding affinity) rarely infect humans and transmit inefficiently from human to human but can cause severe disease.[457,458,613,708] However, both seasonal and pandemic influenza viruses can bind to lower respiratory tract tissues in some individuals and cause severe lower respiratory tract disease, suggesting a role of other viral and host factors. Single mutations in the *HA* gene can change or enhance influenza virus receptor binding affinity and transmissibility in the ferret model.[330] Although the 2009 H1N1 virus did not exhibit predominant receptor binding affinity in the lower respiratory tract, this virus caused increased morbidity and replicated to higher titers in lung tissues in contrast to seasonal influenza A (H1N1) virus in experimentally infected ferrets, mice, and nonhuman primates.[321,444,487] In lower respiratory tract tissues of fatal human cases, 2009 H1N1 virus was found to infect alveolar lining cells, including type I and II pneumocytes.[610] Although seasonal influenza A and B viruses have tropism for the upper respiratory tract, influenza viral pneumonia can occur more commonly in elderly, immunosuppressed individuals and young children, especially with underlying chronic comorbidities, although middle-aged adults can be affected.[150,293,318,489]

Examples of virulence factors include mutations in *HA* (e.g., D222G and D225G),[40,127,419] which also can enhance viral tropism for lower respiratory tract tissues, and presence of the PB1-F2 protein, which can inhibit the induction of type I interferon (IFN) and cause a proinflammatory effect[712]; some PB1-F2 inflammatory phenotypes were associated with pulmonary infection with *S. pneumoniae* or *S. aureus* in the murine model.[11,322] Expression of the 1918 H1N1 virus PB1-F2 protein enhanced pathogenesis and secondary bacterial pneumonia in the murine model.[462] The HA protein of influenza viruses has to be cleaved by host proteases for the virus to be infectious.[373] Presence of a highly basic amino acid sequence in the HA cleavage site of highly pathogenic avian influenza A (H7N7) and (H5N1) viruses is associated with pathogenicity in avian and mammalian species, including humans. Mutations in PA and PB2 can result in enhanced replication of avian influenza A viruses in mammalian cells.[158,488] The NS1 protein of avian influenza A (H1N1) and (H5N1) viruses can induce suppression of innate immune responses and promote apoptosis in human kidney cells in vitro.[484]

Influenza virus infection of respiratory cells triggers activation of innate and adaptive immune responses. Toll-like receptors (TLRs), retinoic acid inducible gene-I *(RIG-I)*, and NOD- nucleotide-binding oligomerization domain (NOD)-like receptor family pyrin domain containing 3 protein (NLRP3) recognize influenza viral RNA.[381] TLR7, TLR3, and RIG-I bind influenza viral RNA and induce production of proinflammatory cytokines (tumor necrosis factor–α, interleukin [IL]-1, IL1β,

and IL-6,) and chemokines (monocyte chemoattractant protein [MCP-1], regulated upon activation normal T cell expressed and presumably secreted [RANTES], and macrophage inflammatory protein [MIP]-1αβ, IP-10, IL-8).[219] Type 1 IFNs (IFN-β, IFN-α) are stimulated, resulting in an antiviral effect on viral replication and by inhibiting protein synthesis in host cells and also stimulate dendritic cells to increase antigen presentation to $CD4^+$ and $CD8^+$ T cells.[219] $CD4^+$, $CD8^+$, and regulatory T cells (Tregs) are induced by influenza virus infection. $CD4^+$ T helper (Th) cells (Th1, Th2) are important components of the adaptive immune response. Th1 cells produce IFN-γ and IL-2 and are involved in cellular immune responses.[381] Th2 cells produce IL-4 and IL-13 and promote B cell responses.[381] Tregs and Th17 cells regulate T helper cell and $CD8^+$ response, and, when induced, Th17 cells produce IL-6 to inhibit Treg function.[381] $CD8^+$ cells are activated in lymphoid tissues and recruited to the site of infection, where they function as cytotoxic lymphocytes and recognize and lyse cells infected by influenza viruses. Natural killer cells can recognize and lyse infected cells bound to antibody. Memory $CD4^+$ and $CD8^+$ T cells contribute to promote the immune response to subsequent influenza virus infection.[168,381] Memory $CD8^+$ T cells can be distributed in the lung, liver, spleen, and bone marrow.[168]

Influenza viral factors allow escape from host innate immunity, and other factors can accelerate tissue damage from influenza virus infection. Binding of viral RNA by NS1 protein helps avoid recognition by TLRs and RIG-I, inhibiting type 1 IFN production.[381] NS1 also can inhibit RIG-I, and NS1, NP, and M2 contribute toward blocking host inhibition of influenza virus protein synthesis and replication.[381] PA-X, a newly described influenza A virus protein, modulates the host innate immune response.[327] Mutations can arise in viral epitopes that are targeted by cytotoxic T lymphocytes, resulting in escape from cellular immunity.[381] Release of chemokines induces neutrophils and T cells to migrate to infected respiratory tissues, which can further contribute to lung injury. MCP-1 mediates migration of alveolar macrophages and monocytes to infected lung tissues, and influenza virus infection of alveolar macrophages leads to apoptosis, whereas infection of epithelial cells causes necrosis.[390] Infected macrophages also can contribute to lung injury by releasing excessive amounts of reactive nitrogen intermediates and reactive oxygen species.[390] In the ferret model, local innate immune responses were temporally correlated with transmission, peak viral shedding, and virulence for influenza viruses that cause a range of disease and transmissability.[442] Cytokine dysregulation ("cytokine storm") has been demonstrated in vitro, and high serum and plasma cytokine levels are often correlated with high viral levels (delayed viral clearance) in the lower respiratory tract, suppression of adaptive and cellular immunity, critical illness (which can include multiorgan failure and hemophagocytosis), and fatal pulmonary disease (e.g., ARDS, pulmonary edema) in patients with seasonal influenza, 2009 H1N1, or HPAI H5N1 virus infections.*

*References 4, 52, 53, 155, 402, 403, 678.

Recently, differences in cytokine production in human macrophages and virulence in mice from highly pathogenic avian influenza A (H5N1) virus infection were attributed to the acidic polymerase (PA) protein, suggesting a viral molecular basis for induction of the host response and complementing the findings of another study that identified a new protein (PA-X) that modulates the host response to influenza A virus infection.[327,593]

Antibodies to the influenza virus HA protein are produced by plasma cells after influenza virus infection and are also induced by influenza vaccination. Memory B cells are virus-specific and are of long duration. The HA inhibition antibodies produced are virus strain-specific and of variable duration, depending on host age, and underlying immune function. Other aspects of the humoral immune response to influenza virus infection are the production of local immunoglobulin (Ig)A and systemic IgG neutralizing antibodies.[168] The concept of "original antigenic sin" was first proposed by Thomas Francis, Jr., to refer to the humoral immune response to the initial influenza virus infection of early childhood that is virus-specific and influences the subsequent humoral immune response to subsequent influenza virus infections.[213] Infection with an antigenically drifted virus stimulates memory B cells to produce antibodies to the initial virus, which may not clear the new virus infection as effectively. However, it has been observed that heterosubtypic immunity can be produced through production of cross-reactive influenza A virus antibodies and T cells. Antibodies to influenza A viruses have been identified that bind broadly to the conserved stem region epitopes of group 1 HA or group 2 HA proteins. This is an area of active research for development of immunotherapy and broadly protective "universal" vaccines.[381]

Host genetic factors may contribute to susceptibility to severe disease outcomes, although most studies have been underpowered. A study using genealogic records linked to death certificate records for a 100-year period in the state of Utah reported that first-, second, and third-degree relatives of a person who died of an influenza-attributable condition had a significantly increased risk for death attributable to influenza than expected.[6] One study of fatal seasonal influenza cases reported that those with low-producing *MBL2* genotypes had a sevenfold risk for invasive methicillin-resistant *S. aureus* (MRSA) than fatal cases with higher producing *MBL2* genotypes.[198] Other family clustering of influenza deaths has been observed with MRSA coinfection[804] and with HPAI H5N1 virus infection.[300,342,601,798] Case reports have identified thermolabile carnitine palmitoyltransferase II (CPT-II) variants as a possible risk factor in influenza-associated encephalopathy in Japanese and Chinese children.[384,445,782] One study reported that *CD55* gene polymorphisms were associated with severe illness from 2009 H1N1 virus infection in Chinese patients.[797] A case-control study reported four single-nucleotide polymorphisms that were associated with severe pneumonia from 2009 H1N1 virus infection located on chromosomes 1 and 17.[800] Evidence of a host genetic susceptibility factor was reported through in vitro, in vivo, and genetic studies of hospitalized influenza patients in the United Kingdom.

A significant number of hospitalized influenza patients had a single-nucleotide polymorphism identified in the IFN-inducible transmembrane *(IFITM3)* gene in contrast to matched European controls.[187] The topic of host genetic factors associated with severe and fatal influenza outcomes is under active investigation.

Histopathologic findings on evaluation of tissues from fatal cases with laboratory-confirmed seasonal or pandemic influenza suggest primary pulmonary and extrapulmonary causes of death for seasonal influenza virus infection in children (Fig. 177-3A to E). One study of tissues from cases of pediatric influenza-associated death identified lung damage (diffuse alveolar damage [26%], extensive secondary bacteria pneumonia [24%], extensive intra-alveolar hemorrhage [22%], viral pneumonitis [22%]), and myocarditis (30%) as causes of death of tested cases.[253] In trachea and bronchi, additional findings included submucosal congestion (90%), submucosal mononuclear inflammation (73%), bronchial epithelium necrosis (50%), submucosal hemorrhage (50%), and eosinophils (40%).[253] In lung tissues, mononuclear interstitial inflammation (67%), hyaline membrane formation (67%), intra-alveolar hemorrhage (54%), and neutrophilic bronchopneumonia were identified.[253] Hemophagocytosis was noted in 53 percent of lymph nodes examined.[253] In a study of fatal influenza B cases, myocardial injury was noted in 69 percent of tested patients, mostly in children; of these, 50 percent had myocarditis and 50 percent had evidence of ischemic myocardial necrosis.[534] In a study of autopsy tissues from 100 fatal cases of 2009 H1N1 virus infection, 80 percent of whom were 20 years of age or older, lung findings included edema (63%), hyaline membranes (59%), fibrin (58%), hemorrhage (58%), inflammation (48%), and neutrophilic bronchopneumonia (29%).[610] Seasonal or pandemic influenza viruses have rarely been isolated or detected outside of the respiratory tract. Very rare isolation of influenza virus has been reported from cerebrospinal fluid (CSF), stool, and myocardium.[166,178,453,557] Infrequent detection of influenza viral RNA from blood, urine, and stool has been reported, but may not necessarily represent viable virus. Detection of viral RNA in stool, including in patients without gastrointestinal symptoms, may represent swallowed virus.[662,679,786]

Clinical Issues

Clinical Characteristics of Uncomplicated Influenza

A wide spectrum of illness in children is associated with seasonal influenza virus infection, ranging from asymptomatic infection to critical illness and death. Asymptomatic infection may vary by age and prior immunity to antigenically similar influenza viruses. Household and seroepidemiologic studies have identified asymptomatic seasonal influenza virus infections in approximately 10 to 30 percent of persons studied,[208,545] and in one study approximately 60 percent of infections were estimated to be asymptomatic.[474] Asymptomatic infection is likely to be less common with pandemic influenza virus infection because of the lower prevalence of prior immunity in contrast to seasonal influenza virus infection.[85,128,209,334,413] Clinical manifestations are influenced by age, underlying immune status, and presence of chronic comorbidities.

Influenza in neonates and young infants may not always be accompanied by temperature elevation, but young infants can have high fever and a sepsis-like syndrome.[49,143,238,425,618] Neonates may manifest apnea and experience symptoms ranging from mild illness to respiratory failure.[455,706,790] In one study over three influenza seasons, one third of hospitalized children with laboratory-confirmed influenza were younger than 6 months of age.[567] Infants younger than 1 year of age can have fever and pneumonia, bronchiolitis, or croup.[346] Premature infants and those with chronic medical conditions may be at increased risk for severe illness.[783]

Common clinical features of influenza in young children, older children, adolescents, and adults are presented in Tables 177-1, 177-2, and 177-3. Diarrhea and vomiting are more common in young children than in older children.[358,417,617] Older children may have sudden onset of fever, nonproductive cough, rhinorrhea or nasal congestion, myalgia, headache, and pharyngitis. Sneezing is uncommon, but can occur. Conjunctivitis can occur infrequently and rashes are rare.[144] Influenza A and B virus infections cannot be distinguished on the basis of clinical signs and symptoms, illness severity, or other respiratory virus infections.[144] High fever is the only consistent sign or symptom that may be suggestive of influenza.[283,517] Vomiting and diarrhea are observed more frequently with influenza B than influenza A.[358,561,766] Atypical presentations in school-age children may include abdominal pain with or without fever.[358]

Influenza Complications

Influenza virus infection of the respiratory tract can result in a wide range of clinical complications. Otitis media is a frequent complication of influenza in young children.* Otitis media, bronchitis, and sinusitis can be managed on an outpatient basis. Mild to moderate exacerbation of underlying medical conditions may be managed on an outpatient basis, but worsening of chronic disease may require hospitalization, including intensive care (e.g., asthma, acute chest syndrome or other sickle cell crises, epilepsy, or cystic fibrosis).† Children with certain comorbidities such as chronic cardiac, pulmonary, neurologic, and neuromuscular diseases are at higher risk for severe pulmonary complications and prolonged hospitalization.‡ However, previously healthy children also can experience fulminant progression of severe influenza complications, including from influenza virus infection alone or from secondary invasive bacterial coinfection. Severe complications require hospitalization and can progress rapidly to death.[56] Epidemiologic studies, hospital cohort studies, and fatal case series have consistently identified children younger than 2 years of age to be at highest risk for hospitalization and death among children.

Respiratory

In young children, influenza virus infection of the respiratory tract can result in bronchiolitis and croup,[73,346,367,535,582,637] although school-age children also can experience croup with influenza.[160] Tracheitis may occur uncommonly, usually with bacterial coinfection.[54,298] Viral pneumonitis and viral pneumonia can occur in all ages, may occur more frequently in immunosuppressed patients, and may vary by virus characteristics. For example, influenza A(H1N1)pdm09 virus is more often associated with viral pneumonitis and pneumonia than other seasonal influenza A or B viruses.[481,683] Radiographic findings of influenza viral pneumonia include bilateral interstitial or patchy infiltrates, diffuse infiltrates, multifocal opacities, and segmental or lobar consolidation (Fig. 177-4A to E])[329,776] Secondary bacterial pneumonia can be associated with fulminant progression to respiratory failure within 2 to 4 days of influenza onset.[201] The most common bacterial pathogens associated with influenza and secondary bacterial pneumonia in the United States are *S. pneumoniae*, *S. aureus* (methicillin-sensitive MSSA, or MRSA), and *S. pyogenes* (group A streptococcus).[201,253,331,515] In other countries, *Haemophilus influenzae* (type B or nontypable) also may be identified. The most fulminant clinical course is usually observed with *S. aureus* coinfection, either *MSSA or MRSA*, and can result in rapid progression to respiratory failure. MRSA was a mortality risk factor in previously healthy children who were critically ill with 2009 H1N1 virus infection.[570] In animal models, a synergistic effect of influenza virus with pneumococcal infections and *S. aureus* infections have been reported.[322,463,464] A report of chest pain in a child with influenza is concerning for secondary bacterial pneumonia. Parapneumonic empyema has been reported with *S. pneumoniae*, *S. aureus*, and 2009 H1N1 virus infection.[16] Status asthmaticus can occur in patients without a prior history of asthma, but is more common in asthmatic children. Spontaneous

pneumomediastinum with pneumonia has been reported.[270,776] Children with second-hand tobacco smoke exposure may be at risk of more severe influenza illness.[745]

Cardiac

Rare complications such as myocarditis and pericarditis are associated with influenza more commonly in young children, but cases can occur in children of all ages with either influenza A or B virus infection of the respiratory tract.* Myocarditis can cause critical and fatal illness, including sudden death, especially in young children. Influenza virus is almost never isolated or detected in the myocardium and is most likely due to an immune-mediated inflammatory process.[253,534]

Neurologic

A wide range of neurologic complications associated with seasonal and pandemic influenza has been reported, ranging from moderate to fatal illness.† Simple febrile seizures may occur in young children, as well as complex partial seizures and status epilepticus.* Transient encephalopathy may be manifested by confusion, incoherence, mutism, and lethargy, with or without fever.[453,503] Influenza-associated encephalopathy (IAE), including with neurologic sequelae or death, has been reported in some countries, most frequently through national surveillance in Japan.[14,482,680] One study reported that treatment with diclofenac (nonsteroidal anti-inflammatory drug), elevated aspartate aminotransferase, blood glucose level of 150 mg/dL or greater, and hematuria or proteinuria, were associated with mortality.[491] A reversible splenial lesion has been reported in some encephalopathy patients.[660] Delirium and visual hallucinations have been described in IAE patients.[351] IAE is thought to be a result of cytokine dysregulation and inflammation and not viral invasion of central nervous system tissue. Encephalopathy and encephalitis may undergo fulminant clinical progression, with hyperpyrexia, elevated intracranial pressure, and uncal herniation observed in some fatal cases. Neuroimaging findings can be normal or show diffuse cerebral edema on computed tomography or magnetic resonance imaging (MRI). A mild pleocytosis may be observed, but the CSF is often normal. Cerebellitis has been described. A subset of encephalopathy, acute necrotizing encephalitis is often manifested by high fever, seizures, altered mental status to loss of consciousness and fulminant progression, with poor clinical outcomes, including neurologic sequelae or death.[470,482,652] Classic findings in acute necrotizing encephalitis are bilateral thalamic lesions on MRI, and brain stem also may be involved. Electroencephalogram may be abnormal.

Influenza-associated encephalopathy is distinguished from Reye syndrome by the absence of hypoglycemia and usually mild to moderate elevated hepatic transaminases.[482] Cases of encephalitis were noted during the 1957 H2N2 pandemic,[755] and encephalopathy with 1957 H2N2 virus infection with fatal outcomes was described in children.[526] Encephalopathy and encephalitis associated with the 2009 H1N1 pandemic were reported worldwide among children of all ages.[218,351,361] Postinfectious influenza encephalopathy with meningismus also has been reported.[502,805] Acute disseminated encephalomyelitis with influenza is uncommon, but has been reported.[532,575,729,785] Guillain-Barre syndrome (GBS) has been reported rarely in children with influenza virus infection and is associated with influenza in adults.[713] Transverse myelitis with influenza also is rare.[393] Rare cases of cerebrovascular accident, including secondary to hypotension, also have been reported.[38,296,502] Isolation of influenza virus from CSF is extremely rare, but has been reported.[453] Similarly, detection of influenza viral RNA in CSF has been reported infrequently, but may not represent viable virus. Aseptic meningitis with influenza has been described.[531] Influenza virus infection of the upper respiratory tract may precipitate secondary bacterial infection, bacteremia, and meningitis, with or without pneumonia. Influenza has been observed to precede outbreaks of meningitis with *Neisseria meningitidis*.[79,87,269]

Musculoskeletal

Myositis with mild to moderate elevations in creatine phosphokinase is common in hospitalized influenza patients. Schoolchildren typically 6 to 9 years of age, and boys more frequently than girls, may experience acute onset of bilateral gastrocnemius and soleus myositis.* Rhabdomyolysis and myoglobinuria can occur.[767] A common complaint is severe bilateral calf muscle pain and inability to walk. Myositis appears to be more commonly associated with influenza B than influenza A.[194,358] Severe myositis can precipitate rhabdomyolysis, acute renal failure, sepsis, disseminated intravascular coagulation (DIC), and compartment syndrome, requiring emergency fasciotomy to prevent muscle necrosis.[625,657]

*References 83, 134, 194, 306, 358, 447.

Hepatic

Mild to moderate elevation of hepatic transaminases can be observed with influenza, and rare cases of acute hepatitis and liver failure have been reported, including in previously healthy children.[743] Elevated transaminases and steatosis are observed with influenza and Reye syndrome, and hepatic failure and death can occur.[37,294,509,640] Reye syndrome with influenza is associated with salicylate exposure and occurs more commonly with influenza B than influenza A virus infection.[37,261,294,509,640] Chronic hepatic disease has been associated with pneumonia from 2009 H1N1 virus infection.[771] One study conducted primarily in adults suggested that hepatic involvement was greater with 2009 H1N1 in contrast to seasonal influenza and was likely the result of hypoxia and hypoxemia.[540]

Renal

Influenza can precipitate renal abnormalities through different mechanisms.[608] Cytokine dysregulation, hypotension, and rhabdomyolysis with myoglobinuria may contribute to acute renal dysfunction and failure.[159,239,435,608] Patients who are critically ill with influenza viral pneumonia, respiratory failure, and refractory hypoxemia may experience multiorgan dysfunction, including renal failure.[570,734]

Bacterial Coinfection

Most influenza virus infections do not result in secondary invasive bacterial infection. Uncommonly, young infants may experience urinary tract bacterial infection,[383,425] and serious bacterial infections are less frequent in nonhospitalized febrile young children with influenza in contrast to those without influenza.[634] However, secondary invasive bacterial infections associated with seasonal or pandemic influenza may result in bacteremia and sepsis and cause critical illness and fatal outcomes.[667,791] Secondary bacterial pneumonia is the most common serious bacterial complication associated with influenza. In the United States, the most common bacterial pathogens causing pneumonia, bacteremia, and sepsis associated with influenza virus infection reflect nasopharyngeal carriage and subsequent invasive infection: *S. pneumoniae*, *S. aureus* (MSSA or MRSA), and *S. pyogenes* (group A streptococcus).* In other countries, *H. influenzae* (type B or nontypable) also may be identified. The most fulminant clinical course is usually observed with invasive *S. aureus* infection, either MSSA or MRSA.[201] *N. meningitidis* infection resulting in meningococcemia or meningitis can follow influenza virus infection.[79,87,194,201,269]

Sepsis and Disseminated Intravascular Coagulation

Sepsis and DIC can be precipitated by influenza virus infection of the respiratory tract, with or without bacterial infection, leading to critical and often fatal outcomes.[435,689] Toxic shock syndrome with influenza and toxin-producing *S. aureus*, with tracheitis or pneumonia, can lead to critical illness and death.[440]

Viremia

Viremia with influenza virus infection has been poorly studied. However, studies of blood donated to blood banks during pandemics and other limited studies suggest that seasonal or pandemic influenza viremia is extremely rare in uncomplicated disease and critical illness. Isolation of influenza A (H3N2) virus was reported from blood and throat specimens of an individual collected 12 hours before illness onset during the 1968 H3N2 pandemic.[359] Isolation of 1957 H2N2 virus from extrapulmonary tissues (i.e., spleen, liver, kidney, and heart) in two fatal cases suggested viremia.[341] The 1957 H2N2 virus was isolated from myocardial suspension without histologic changes except in the arterioles.[526] Viremia with seasonal influenza virus infection has been reported rarely.[341,359,440] Viremia was identified during the incubation period in experimentally infected volunteers.[691] Detection of 2009 H1N1 viral RNA in blood specimens of hospitalized patients during the 2009 H1N1 pandemic was reported.[530,688] Studies that tested banked blood for evidence of 2009 H1N1 viral RNA during the pandemic did not find evidence of viremia.[459,635,646] The largest autopsy case series of fatal 2009 H1N1 patients did not find evidence of extrapulmonary dissemination.[610] Viremia has been identified in fatal human infection with highly pathogenic avian influenza A (H5N1) virus.[81,154,155,806]

Vertical Transmission

Seasonal influenza virus infection of pregnant women does not appear to result in vertical transmission.[317] Rare case reports suggesting vertical transmission have not conclusively proved that seasonal or pandemic influenza viremia has occurred, with subsequent transmission to the fetus.[115,172,345] Vertical transmission has been demonstrated in human infection with highly pathogenic avian influenza A (H5N1) virus.[806]

Sudden Death

Sudden death can occur after a brief mild influenza illness.[56] For some children without underlying comorbidities, autopsy findings may include evidence of diffuse alveolar damage without bacterial infection or myocarditis.[253] In some cases, encephalitis or cerebral edema with concomitant pneumonia are identified. Autopsy findings may not identify a clear etiology for death, suggesting the possibility of an arrhythmia or other cause of cardiac failure. Fulminant cases of bacterial sepsis with influenza also have been reported.

CLINICAL MANAGEMENT

Clinical Diagnosis

Influenza may not always be accurately diagnosed based on clinical presentation from other etiologies of acute febrile respiratory illness with or without fever, if other pathogens, especially noninfluenza respiratory viruses, are co-circulating in the community.[549] Signs and symptoms associated with higher odds ratios or positive predictive values for influenza in children include high fever (temperature >39.0° C [>102.0° F]) and cough.[283,517,617] Many other co-circulating respiratory viruses can cause influenza-like illness, including rhinoviruses, coronaviruses, adenoviruses, parainfluenza viruses, bocaviruses, human metapneumoviruses, respiratory syncytial viruses, and others. Although testing is not necessary to diagnose influenza in every patient, especially during high influenza activity in a community, some testing can be beneficial to establish that influenza virus infections are present in the patient population. Influenza A and B virus

*References 8, 56, 201, 331, 610, 667.

infections cannot be distinguished by clinical signs and symptoms.[144]

Diagnostic Testing

Several diagnostic tests for the qualitative detection of influenza viruses are commercially available,[385] although the sensitivities to detect influenza viruses can vary widely and clinicians should be aware of many factors influencing testing results and the limitations of available diagnostic tests.

Specimens for Influenza Testing

For symptomatic outpatients with suspected influenza, upper respiratory tract specimens should be collected within 3 to 4 days of illness onset for influenza testing. Collection of respiratory specimens later in the clinical course still may yield detection of influenza viruses from young infants, immunosuppressed patients, and those with severe illness resulting from prolonged influenza viral replication, by use of molecular assays. For detection of seasonal or pandemic influenza A and B viruses, the optimal upper respiratory tract specimens are nasopharyngeal aspirates from infants and young children and nasopharyngeal swabs from school-age children.[281] Nasal washes or combined nasal and throat swabs also may have high yield for influenza viruses.[156,280,366] The lowest yield for influenza viruses for viral isolation is from throat swabs alone. However, molecular assays may detect influenza viral RNA for longer periods than other assays, including in throat swabs. For hospitalized patients with respiratory failure, lower respiratory tract specimens (e.g., endotracheal aspirates) should be collected for influenza testing, especially if testing of upper respiratory tract specimens is negative, because influenza viral replication is longer in the lower respiratory tract than in the upper respiratory tract in patients with lower respiratory tract disease.[35,699] Bronchioalveolar lavage fluid, if obtained for other diagnostic purposes, also can be tested. Clinicians should consult laboratory colleagues or the test manufacturer's package inserts for the acceptable swabs and approved clinical specimens. Swabs used for specimen collection should have a Dacron tip and an aluminum or plastic shaft. In general, swabs with calcium alginate or cotton tips and wooden shafts are not recommended for any influenza testing because specimens collected with these swabs may produce inaccurate results.

Available Assays

For outpatients and emergency department patients, the most common commercially available assays are rapid influenza diagnostic tests (RIDTs) that detect influenza virus antigens in respiratory specimens. The majority of RIDTs are enzyme immunoassays that use monoclonal antibodies against influenza viral nucleoprotein (a conserved protein) to produce a result in approximately 10 to 15 minutes. The advantages of RIDTs are that they are simple to perform and produce a quick result. Some tests may not distinguish between influenza A and B viruses, although most tests can differentiate between influenza A and B using separate type-specific monoclonal antibodies. None of the RIDTs can differentiate between influenza A virus subtypes, whether of human (i.e., seasonal influenza viruses) or animal origin (i.e., swine or avian influenza A viruses). Most RIDTs are available in kits that contain antigen extraction reagents, swabs, and indicator devices that generally fit in the palm of a hand. The disadvantages are that RIDTs have generally poor to moderate sensitivities to detect seasonal, pandemic, and novel influenza A viruses in contrast to molecular assays or viral culture and produce limited information (influenza virus type).* In the United States, most RIDTs are approved for point-of-care use, but some must be performed in a moderately complex clinical laboratory. Recently, RIDTs have become available that use a reader device to improve test sensitivity. One fluorescent lateral flow immunoassay employs a cartridge and analyzer device to improve test sensitivity. Use of influenza RITDs in outpatients yielding positive results have reduced patient time spent in the emergency department, ordering of other diagnostic tests and antibiotics, and cost.[65,511,556] Other studies have reported that empirical antiviral treatment is more cost-effective than using RIDTs for antiviral treatment decisions.[396,585]

Other antigen detection tests include immunofluorescent assays (direct florescent antibody staining [DFA], and indirect florescent antibody staining [IFA]) that use influenza virus type-specific florescent-tagged monoclonal antibodies visualized through a florescent microscope. Turnaround time to results is approximately 2 to 3 hours and is more commonly available in hospital clinical laboratories. Some respiratory virus immunofluorescence panels are available that detect influenza A and B virus antigens and other respiratory viruses. Collection of a good-quality respiratory specimen containing epithelial tissue is important to improve test performance. Sensitivity to detect influenza A viral antigen is generally slightly higher than for detecting influenza B viral antigen, and most studies of immunofluorescence assays have reported a range of sensitivities of 70 to 90 percent versus viral culture.[700] Neither DFA nor IFA can produce results other than identifying influenza virus type.

Molecular assays that can detect influenza virus nucleic acid using different platforms are becoming more commonly available in hospital clinical laboratories.[714] Some molecular assays can differentiate between influenza A and B viral RNA, and some may use different primers and probes to distinguish between some influenza A virus subtypes. The commonly available assays use RT-PCR, including some assays that detect only influenza viral RNA, and other multipathogen assays that may detect a variety of respiratory viruses; some assays may detect many viruses and bacteria associated with respiratory illness. State public health laboratories in the United States use the CDC FLU rRT-PCR FLU Dx Panel, which can detect influenza A, B, H1, H3, H5, influenza A(H1N1)pdm09, and A/pdm09.[615] Deployment of this assay worldwide allowed detection of influenza A(H1N1) pdm09 virus infections throughout the 2009 H1N1

*References 31, 102, 119, 190, 699, 700, 704.

pandemic.[335] In general, molecular assays such as rRT-PCR have the highest sensitivities to detect influenza viruses in respiratory specimens in contrast to other influenza tests.

Viral culture of respiratory specimens is the most specific influenza test, but the sensitivity of viral culture to isolate influenza viruses, although high, is lower than the sensitivity of molecular assays to detect influenza viral RNA. This is because viral culture can isolate only viable influenza viruses, whereas molecular assays can detect the presence of virus, but not necessarily replicating virus. Viral culture may be done at some hospital clinical laboratories, but is generally performed at public health laboratories. Some clinical laboratories may perform shell vial tissue cell culture to produce results in 24 to 48 hours. Routine tissue cell viral culture generally requires 3 to 7 days. Most viral culture for influenza viruses is performed by inoculation of Madin-Darby canine kidney (MDCK) tissue cells, but other tissue cell lines are used for culture of a wider range of respiratory viruses.

Public health laboratories such as national influenza centers and WHO Collaborating Center laboratories also isolate influenza viruses using embryonated eggs for vaccine candidates because most influenza vaccine strains are selected and prepared from egg-grown viruses. Isolation of viruses allows for detailed virologic characterization, including antigenic properties, genetic analyses, antiviral biologic assays, structural analyses (e.g., receptor binding analyses). Pyrosequencing assays can be used for determination of the presence of known virulence markers for research purposes.[407] Full genomic sequencing is essential to assessing genetic reassortment and presence of known and unknown mutations associated with virulence, antiviral resistance, transmissibility, receptor binding affinity, and other viral characteristics.

Antiviral resistance testing is important for public health and for clinical management of influenza patients who are at increased risk for emergence of antiviral resistance. Routine testing of viruses for antiviral susceptibility is an important component of influenza surveillance worldwide. During 2003 to 2006, a substantial global increase in the prevalence of influenza A viruses resistant to the adamantane antivirals (i.e., amantadine and rimantadine) was identified through pyrosequencing, leading to the recommendation not to use these antiviral drugs for influenza A.[71,72,163] During 2007 and 2008, influenza A (H1N1) viruses with an H275Y mutation in viral neuraminidase associated with oseltamivir resistance became widely prevalent; these viruses are no longer circulating and were replaced by the emergence of influenza A(H1N1)pdm09 virus.[272,391,468] During the 2009 H1N1 pandemic, oseltamivir resistance was identified sporadically, most often during or after oseltamivir treatment in immunosuppressed patients or during oseltamivir chemoprophylaxis.[310] Some human-to-human spread and community transmission of influenza A(H1N1)pdm09 viruses with the H275Y mutation in neuraminidase have been identified since 2009.[121,310,311,397,476]

Current public health laboratory monitoring for antiviral susceptibility in circulating influenza viruses includes pyrosequencing for known markers associated with antiviral resistance and functional phenotypic assays such as the neuraminidase inhibition assay using live viruses combined with full genetic sequencing to identify known and new markers of antiviral resistance.* Such assays can be performed only at specialized laboratories, national influenza centers, and WHO Collaborating Center laboratories. The WHO has published criteria for classifying neuraminidase inhibitor resistance on the basis of relative differences in inhibitory concentration $(IC)_{50}$ determined in neuraminidase inhibition assays.[764] However, for clinical management purposes, especially for severely immunosuppressed patients at higher risk for prolonged influenza, viral replication and emergence of antiviral resistance during or after treatment, antiviral resistance testing is not widely available. A limited number of laboratories can perform pyrosequencing testing for known markers of antiviral resistance such as H275Y in viral neuraminidase.

Influenza virus serologic testing currently has no role in the clinical management of influenza patients and should not be ordered for many reasons. No validated commercially available IgG or IgM serologic assays, including enzyme-linked immunosorbent assay, exist for detection of influenza virus antibodies. Furthermore, serologic results of a single acute serum specimen are uninterpretable for clinical use. Standard serologic testing for seasonal influenza viruses requires appropriately timed, paired acute and convalescent serum specimens to determine virus strain–specific HAI antibodies and must be performed at special influenza research or public health laboratories. Research laboratories and some public health laboratories can perform microneutralization assays to determine neutralizing antibodies to specific influenza viruses. Seropositive results for either HAI or neutralizing antibodies are considered when a fourfold rise in antibodies is observed in paired serum specimens. Serologic testing can establish a retrospective diagnosis of influenza virus infection, but must be performed by a specialized laboratory. Applications of influenza serologic testing include seroepidemiologic investigations, as well as vaccine immunogenicity and vaccine effectiveness studies. Seroepidemiologic public health investigations can yield data on seroprevalence and seroincidence of strain specific and cross-protective antibodies for infections with seasonal, animal-origin, and pandemic influenza viruses.[101,265,768]

Interpretation of Testing Results

Clinicians should consider many factors that can influence testing results and understand the inherent limitations of influenza tests to properly interpret results, especially from rapid influenza diagnostic tests or other antigen detection tests. These factors include the time from illness onset to specimen collection and the likelihood that influenza viral replication is occurring and viruses can be detected, the kind of specimen that is collected (i.e., swab, aspirate, or wash), the kind of swab used (e.g., Dacron, cotton, or flocked or nonflocked), the specimen source (i.e., nasopharynx, nasal, throat, or

*References 161, 162, 254, 309, 312, 518, 609.

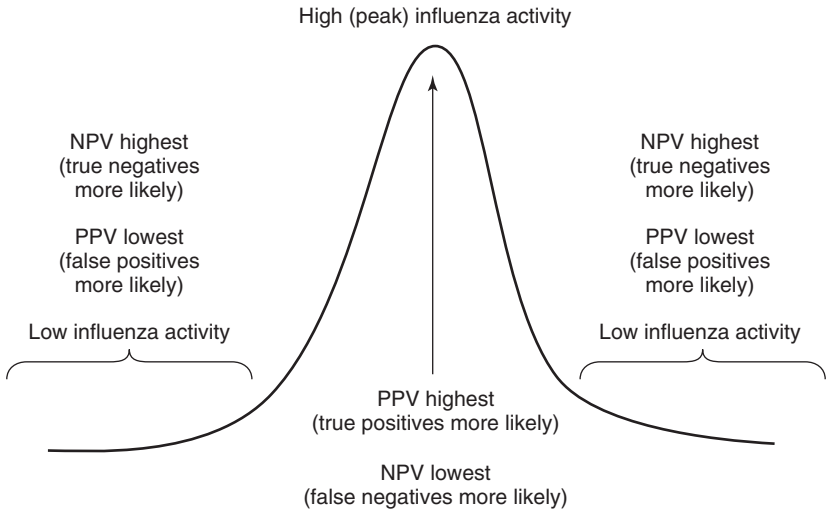

FIGURE 177-5 ■ Prevalence of influenza viruses (influenza activity in the community) and relationship to positive predictive value (*PPV*) and negative predictive value (*NPV*) of influenza diagnostic testing results.

lower respiratory tract), the quality of the specimen collected, and the time from specimen collection to testing, including how specimens are stored and processed (e.g., freeze-thawing) before testing.[700] Inherent fixed properties of tests are the sensitivity and specificity compared with a gold standard assay such as RT-PCR. Furthermore, antigen detection tests (e.g., RIDTs and immunofluorescence) cannot differentiate among influenza A virus subtypes or among seasonal, pandemic, or novel influenza A virus infections. Although specificity may be high, sensitivity of rapid influenza diagnostic tests to detect seasonal, pandemic, and novel influenza A viruses may be poor to moderate, resulting in many false negative results.* One meta-analysis of RIDTs reported that although overall sensitivity to detect influenza viruses was moderate (62.3%) with high specificity (98.2%) in contrast RT-PCR or viral culture, sensitivity was higher for detection of influenza A virus (64.6%) than for influenza B virus (52.2%) and sensitivity was higher in specimens collected from young children (66.6%) than in adults (53.9%).[119]

The prevalence of seasonal influenza viruses circulating in the population being tested is variable.[248,700] The predictive values of tests are calculated based on sensitivity, specificity, and prevalence. Because predictive values vary by influenza virus prevalence, the positive predictive value (PPV) of an influenza test is highest (likely to be "true positives") during peak influenza activity and the PPV is lowest (likely to be "false positives") during periods when influenza viruses are not circulating or activity is very low (e.g., summer in temperate climate countries)[248,700] (Fig. 177-5). Conversely, the negative predictive value (NPV) of an influenza test is highest (likely to be "true negatives") during periods when influenza viruses are not circulating or activity is very low, and the NPV is lowest (likely to be "false negatives") during peak influenza activity. Testing results can vary by influenza virus type, influenza A virus subtype, virus strains, and novel influenza A viruses of animal origin that sporadically infect humans.* Clinicians also should realize that the respiratory tract in a patient with influenza virus infection comprises a population of replicating viruses (quasispecies), and that sampling, amplification, and genetic sequencing may identify a mixed population or a dominant population that is amplified or isolated from the respiratory sample collected.

Antiviral Treatment

In the United States, four prescription influenza antiviral drugs are approved, with different dosing and age-based recommendations.[202] The adamantane antivirals, amantadine and rimantadine, are chemically similar drugs that appear to block the ion channels of the M2 protein of influenza A viruses, but they do not have any activity against influenza B viruses. Both amantadine and rimantadine are approved for chemoprophylaxis of influenza A in children 1 year of age or older. Amantadine is approved for treatment of influenza A in children 1 year of age and older, and rimantadine is approved for treatment of influenza in adults. Gastrointestinal and neuropsychiatric adverse effects have been reported with both drugs, more frequently with amantadine.[202] When used for treatment of susceptible influenza A virus infection, a reduction of viral shedding is observed with early treatment (within 48 hours after illness onset) versus placebo, but rapid emergence of antiviral resistance to amantadine and rimantadine can develop in treated patients.† Since 2006, the CDC has recommended that amantadine and rimantadine not be used for influenza A because of the high prevalence of circulating influenza A viruses that are resistant to these drugs. Similarly, the WHO does not recommend use of amantadine or rimantadine for treatment of influenza A virus infections. One exception is treatment of severe illness resulting from novel influenza A virus infection with documented susceptibility to

Modified from Fiore AE, Fry A, Shay D, et al; Centers for Disease Control and Prevention (CDC). Antiviral agents for the treatment and chemoprophylaxis of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep* 2011;**60**:1-24.

*Zanamivir is manufactured by GlaxoSmithKline (Relenza: inhaled powder). Zanamivir is approved for treatment of persons aged ≥7 years and approved for chemoprophylaxis of persons aged ≥5 years. Zanamivir is administered through oral inhalation by using a plastic device included in the medication package. Patients will benefit from instruction and demonstration of the correct use of the device. Zanamivir is not recommended for those persons with underlying airway disease. Oseltamivir is manufactured by Roche Pharmaceuticals (Tamiflu: tablet). Oseltamivir is approved for treatment of persons 14 days of age and older and for chemoprophylaxis of persons aged ≥1 year. Oseltamivir is available for oral administration in 30-, 45-, and 75-mg capsules and liquid suspension. This information is based on data published by the Food and Drug Administration, available at http://www.fda.gov/Drugs/DrugSafety/InformationbyDrugClass/ucm100228.htm.

†Recommended duration for antiviral treatment is 5 days. Longer treatment courses can be considered for patients who remain severely ill after 5 days of treatment.

‡For control of outbreaks in long-term care facilities and hospitals, the CDC recommends antiviral chemoprophylaxis for a minimum of 2 weeks and up to 1 week after the most recent known case was identified.

§The CDC and ACIP recommend oseltamivir treatment for children of all ages, including from birth. The recommended oseltamivir treatment dosing for infants <1 year is 3 mg/kg/dose twice daily. A reduction in the dose of oseltamivir is recommended for persons with creatinine clearance <30 mL/min.

‖The treatment dosing recommendation for oseltamivir for children aged ≥1 year who weigh ≤15 kg is 30 mg twice per day. For children who weigh >15 kg and up to 23 kg, the dose is 45 mg twice per day. For children who weigh >23 kg and up to 40 kg, the dose is 60 mg twice per day. For children who weigh >40 kg, the dose is 75 mg twice per day.

¶For children ages 3 months to <1 year, the recommended chemoprophylaxis dosing for oseltamivir is 3 mg/kg/dose once daily. The chemoprophylaxis dosing recommendation for oseltamivir for children aged ≥1 year who weigh ≤15 kg is 30 mg once per day. For children who weigh >15 kg and up to 23 kg, the dose is 45 mg once per day. For children who weigh >23 kg and up to 40 kg, the dose is 60 mg once per day. For children who weigh >40 kg, the dose is 75 mg once per day.

NA, Not approved.

amantadine and rimantadine in which one of these drugs may be used as combination antiviral treatment with an NA inhibitor drug.[760]

Two NA inhibitor drugs, oseltamivir and zanamivir, are approved for use in children (Table 177-4). These drugs bind to the NA protein of influenza A and B viruses, inhibiting the release of influenza virions from the infected host cell. Oseltamivir is administered orally and is available in a suspension for young children and in capsules for older children. Oseltamivir is approved for treatment (twice daily) of influenza in children 14 days of age and older and chemoprophylaxis (once daily) of influenza in those 1 year of age and older in the United States. The CDC and WHO recommend oseltamivir for treatment of influenza in children of all ages. Small case series have reported use of oseltamivir treatment or chemoprophylaxis in premature infants and neonates with few serious adverse events.* After oral absorption, the metabolite oseltamivir carboxylate is metabolized by renal clearance. The most common adverse events in children are nausea and vomiting.[742] Rare episodes of neuropsychiatric events have been reported in Japanese adolescents, although it is unclear whether such events are associated with influenza virus infection or oseltamivir.[62,89,664,698] Resistance to oseltamivir can emerge frequently in seasonal influenza A (H1N1) viruses (no longer circulating) and infrequently in influenza A (H3N2) viruses during or after treatment in children.[370,645,663] Resistance is more likely to emerge in severely immunosuppressed patients with prolonged viral replication.[223,309] The most common mutation associated with oseltamivir resistance is the H275Y mutation in viral neuraminidase.[310] Reduced oseltamivir susceptibility and lower clinical effectiveness has been noted in some influenza B virus infections.[271,654]

RCTs have reported efficacy of oral oseltamivir versus placebo in treatment of uncomplicated influenza in pediatric outpatients when treatment is started within 48

*References 2, 450, 467, 539, 639, 686.

hours after illness onset. Systematic reviews and meta-analyses of RCTs have reported approximately a 21-hour to 1.5-day reduction in the duration of influenza illness of early oseltamivir treatment.[133,332,727] Early oral oseltamivir treatment of influenza in children can reduce the risk for otitis media.[284,742] A meta-analysis of 11 RCTs of early oseltamivir treatment in adolescents and adults with uncomplicated influenza found a 37 percent reduced risk for lower respiratory tract complications requiring antibiotic treatment in patients with confirmed influenza versus placebo.[287] As of 2012, no data from placebo-controlled RCTs were available for oseltamivir treatment of hospitalized pediatric influenza patients. Observational studies of oseltamivir treatment of hospitalized children with influenza have reported a reduction in duration of hospitalization and lower risk for severe complications requiring mechanical ventilation.[130,182] Critically ill patients with respiratory failure can be administered oseltamivir enterically via a nasogastric or orogastric tube. Very limited data suggest that oseltamivir may be absorbed in such patients.[230,744] Observational studies of oseltamivir effectiveness in influenza patients of all ages and in adults, including pregnant women, have consistently reported a significant reduction in the risk for critical illness and death when oseltamivir treatment was started up to 5 days after seasonal or pandemic influenza illness onset, with the greatest clinical benefit observed when oseltamivir treatment was started within 48 hours after illness onset.[305,428,623,780,788] This suggests that although early treatment is most effective, later initiation of oseltamivir treatment, including for hospitalized influenza patients, can still have some clinical benefit.

The CDC recommends empirical oseltamivir treatment of hospitalized patients of all ages with suspected influenza as soon as possible without waiting for influenza testing results.[202] Empirical NA inhibitor treatment (with oseltamivir) is also recommended as soon as possible for pediatric outpatients of all ages with suspected influenza who are considered at high risk for influenza complications (i.e., children younger than 5 years; those of any age with chronic pulmonary, cardiac, metabolic, hematologic, renal, neurologic, neuromuscular, or neurodevelopmental conditions; and those receiving chronic aspirin therapy). Although children younger than 5 years of age are considered at high risk for influenza complications, the highest risk is for children younger than 2 years, and clinical judgment is advised when treating children 2 through 4 years of age with suspected influenza who are otherwise healthy.[202] Children 5 years of age and older with suspected influenza who are not considered to be in a high-risk group can be treated based on clinical judgment if oseltamivir treatment can be started within 48 hours after illness onset.[202] Pediatric patients with highly suspected or documented oseltamivir-resistant influenza virus infection should receive inhaled zanamivir treatment, if treatment is indicated and not contraindicated by age, underlying chronic pulmonary disease, or intubation. Limited data suggest that severe illness with oseltamivir-resistant influenza virus infection (influenza A[H1N1]pdm09 virus) may respond to treatment with the investigational drug intravenous zanamivir. For hospitalized children in whom inhaled zanamivir is contraindicated, the investigational drug intravenous zanamivir should be considered.

One RCT of oseltamivir chemoprophylaxis for 12 weeks in liver, kidney, or liver and kidney transplant or allogeneic hematopoietic stem cell transplant recipients 1 year of age or older, primarily adults, reported a reduction of 80 to 90 percent versus placebo in laboratory-confirmed influenza virus infection.[320] Oseltamivir was well-tolerated, and one oseltamivir-resistant 2009 H1N1 virus infection was identified in each of the treatment and placebo groups. Although routine antiviral chemoprophylaxis is not recommended, oseltamivir chemoprophylaxis of some schoolchildren during the 2009 H1N1 pandemic had variable compliance because of adverse events.[371,648,709,723]

Zanamivir is a powdered drug and is administered using an inhaler device. Zanamivir is approved for treatment (two inhalations twice daily) of influenza in children 7 years of age and older and for chemoprophylaxis (two inhalations once daily) of influenza in those 5 years of age and older in the United States. In some countries, inhaled zanamivir is approved for treatment of influenza in children 5 years of age and older. In younger children, inhaled zanamivir cannot be effectively delivered using the proprietary disk inhaler device. RCTs of early inhaled zanamivir treatment in children and adolescents with uncomplicated influenza have shown a reduction of 1.25 to 2.5 days in illness duration in contrast to placebo.[278,446,727] Although nausea and vomiting can occur with inhaled zanamivir, no significant differences in adverse events versus placebo were reported in RCTs.[278,446] Postmarketing studies have reported bronchospasm in some inhaled zanamivir recipients, and zanamivir is contraindicated in patients with underlying chronic pulmonary disease.[362] The inhaled zanamivir formulation should not be administered to intubated patients because it may precipitate and clog the ventilator tubing, resulting in death.[362,642] As of 2012, no data from placebo-controlled RCTs were available for inhaled zanamivir treatment of hospitalized pediatric influenza patients. Emergence of influenza viruses resistant to zanamivir during or after treatment is rare and much less frequent than the frequency of oseltamivir resistance during and after oseltamivir treatment of influenza.[663] Laninamivir is a long-acting inhaled NA inhibitor that is chemically similar to zanamivir and approved for treatment of influenza in Japan. Treatment with inhaled laninamivir consists of a single dose, which is equivalent to a 5-day twice daily treatment course of oral oseltamivir or inhaled zanamivir.[349,655]

No intravenous NA inhibitors are approved in the United States, but some have been approved in a few other countries. Investigational intravenous NA inhibitors in development include intravenous zanamivir and intravenous peramivir. Intravenous zanamivir is available for compassionate use through an emergency investigational new drug approval application to U.S. Food and Drug Administration (FDA) and the manufacturer. In the United States, intravenous zanamivir and intravenous peramivir may be available through clinical trials through an investigational new drug approval application. Intravenous NA inhibitors have been administered to hospitalized seasonal and pandemic influenza patients,

especially those who are critically ill, although data for pediatric patients are limited.* The WHO suggests that intravenous zanamivir be considered where available for treatment of highly suspected or demonstrated oseltamivir-resistant influenza virus infection.[171,223,760] Dosing with intravenous NA inhibitors may need adjustment for weight, reduced creatinine clearance, hemodialysis, hemofiltration, or extracorporeal membrane oxygenation (ECMO).

Corticosteroids

Corticosteroids are not indicated for the routine clinical management of uncomplicated or complicated influenza, although most data are derived from studies in adults. Observational studies have reported no clinical benefit of corticosteroids in treatment of influenza. Early administration of glucocorticoids was associated with increased risk for severe illness and mortality with influenza A(H1N1)pdm09 virus infection in China.[264] In critically ill influenza patients with respiratory failure or ARDS, administration of corticosteroids did not improve survival, increased the risk for hospital-acquired pneumonia, and increased the risk for death in some studies.† Corticosteroid therapy is associated with prolonged influenza viral shedding.[66,228,401] Although administered for a potential immunomodulatory effect, high-dose corticosteroids can result in immunosuppression with increased risk for severe complications, including nosocomial bacterial or fungal infections. However, low-dose corticosteroids may be indicted for septic shock or refractory, vasopressor-dependent shock with suspected adrenal insufficiency. Corticosteroids have been associated with either no benefit in reducing disease progression or increased mortality in patients with highly pathogenic avian influenza A (H5N1) virus infection.[290,412] Pulsed high-dose corticosteroids have been administered to patients with influenza-associated encephalitis, although clinical trial data are unavailable.[352] Corticosteroids should not be withheld from influenza patients who are receiving chronic corticosteroid therapy, such as for chronic pulmonary, rheumatologic, or other disorders.

Salicylates

Salicylates (aspirin) and salicylate-containing medications should not be administered to children with suspected or confirmed influenza because of the risk for Reye syndrome.[509,640] The incidence of Reye syndrome has declined markedly in the United States since the 1980s, when the association between aspirin ingestion and influenza resulting in Reye syndrome was recognized.[37,261] Children receiving short-term or long-term aspirin therapy for underlying disease (e.g., Kawasaki disease, cerebrovascular ischemia, or congenital cardiac disease) should receive annual influenza vaccination; if influenza is suspected, early antiviral treatment should be administered, with close monitoring for the potential development of Reye syndrome.

*References 118, 288, 429, 636, 653, 789.
†References 78, 164, 368, 369, 456, 770.

Investigational Therapies

Investigational agents in development include monotherapy with an oral polymerase inhibitor (favipiravir T-705), inhaled sialidase (Fludase DAS101), long-acting inhaled NA inhibitor (laninamivir), intravenous NA inhibitors (peramivir or zanamivir), and triple combination antivirals (amantadine, oseltamivir, or ribavirin).[64,275,304] Optimal dosing and duration of antiviral treatment for hospitalized and critically ill children of all ages with influenza has not been determined, and more data are especially needed for treatment of neonates, premature infants, and children younger than 1 year of age. The most appropriate clinical and virologic outcomes in trials of antiviral treatment of hospitalized influenza patients are unclear.[319] Observational studies of immunomodulator therapy of influenza have shown mixed results, and no clinical trial data are available.[325,388,711] Immunotherapy with convalescent plasma, hyperimmune plasma, monoclonal or polyclonal antibodies with broad-spectrum neutralizing activity are in development.*

Supportive Care

Although data from randomized clinical trials are generally lacking, early administration of supplemental oxygen is recommended for hypoxia in influenza patients with acute respiratory distress. Close monitoring of respiratory status is critical because influenza patients with pneumonia or pneumonitis can progress very rapidly to respiratory failure. Pulse oximetry monitoring should be done in the emergency department or clinic at presentation, and continued on inpatient wards. Fluid management is important because some influenza patients may be severely dehydrated, leading to hypovolemic shock. Vasopressors may be required for septic shock and DIC, with or without secondary invasive bacterial infection. Low-dose glucocorticoids may be indicated in refractory septic shock with suspected adrenal insufficiency. Hypovolemic shock may result from vascular permeability (i.e., capillary leakage) caused by cytokine dysregulation (cytokine storm) triggered by influenza virus infection of the respiratory tract. Cardiogenic shock may occur from rare cases of myocarditis or exacerbation of underlying congenital cardiac disease, requiring management by pediatric cardiologists and intensivists.

Management of Complications: Special Issues

Suspected Invasive Bacterial Infection

If secondary invasive bacterial infection is suspected (e.g., bacteremia, sepsis, or pneumonia), empirical intravenous antibiotic treatment should be administered immediately to cover the most likely bacterial pathogens based on underlying host conditions (e.g., cystic fibrosis, asplenia, or immunosuppression), local microbiologic data, carriage data, and antibiotic susceptibilities. In the United

*References 135, 176, 308, 382, 434, 741, 750, 795.

States, the most frequently identified invasive bacterial infections associated with influenza in children without underlying chronic conditions are *S. aureus*, *S. pneumoniae*, and *S. pyogenes*. Initial empirical antibiotic coverage should treat MRSA.[418] In other countries, initial treatment for *H. influenzae* also should be considered in patients with secondary bacterial pneumonia. If meningitis is suspected, empirical antibiotics should also cover *N. meningitidis*.

Renal Insufficiency or Failure

In critically ill children with influenza, renal insufficiency or renal failure may develop, requiring close monitoring of fluid and electrolyte status. Patients requiring renal replacement therapy with hemofiltration or dialysis may need adjustments to antiviral and antibiotic dosing.

Respiratory Failure and Acute Respiratory Distress Syndrome

Although noninvasive ventilation may be attempted initially, influenza viral pneumonia, especially resulting from influenza A(H1N1)pdm09 virus infection, is likely to progress to require invasive mechanical ventilation.[35,193] Progression to ARDS with refractory hypoxemia should be managed according to evidence-based guidelines. During the 2009 H1N1 pandemic, many ARDS cases were treated with a range of rescue strategies (e.g., prone positioning, high-frequency oscillatory ventilation, inhaled nitric oxide, and ECMO).[35,193,570] Without controlled trials, the relative benefits of such rescue strategies for influenza-associated ARDS are unknown. Corticosteroids and other immunomodulators have not been shown to be of clinical benefit in most observational studies of ARDS with influenza. Plasma exchange was used for the purpose of cytokine reduction in a small number of critically ill pediatric patients with 2009 H1N1 virus infection and ARDS.[544] However, the effectiveness of this investigational therapy is unknown.

Encephalopathy and Encephalitis

Currently, no data from RCTs are available for treatment of IAE or encephalitis. Progression from mild, uncomplicated influenza illness to altered mental status with or without seizures may occur rapidly or within 1 to 4 days after illness onset.[352,482] In fulminant cases, progression to increased intracranial pressure (ICP), uncal herniation, and brain death can occur within 1 to 3 days after initial onset of fever.[353] Clinical management is largely supportive, including anticonvulsant therapy for status epilepticus, and intensive care unit management of possible increased ICP. A range of uncontrolled therapies have been administered to children with influenza-associated encephalopathy or encephalitis in Japan, including antivirals, intravenous pulse methylprednisolone, hypothermia induction intravenous immunoglobulin, plasmaphoresis, edaravone, cyclosporine, antithrombin III, and other treatments, but the relative effectiveness of these interventions is unknown.[352,353,482,680] Most Japanese pediatric patients with influenza-associated encephalitis, including acute necrotizing encephalitis, are administered pulse methylprednisolone as soon as possible.[352] Early initiation of antiviral treatment with NA inhibitor drugs is recommended, although the effectiveness of antiviral treatment in patients with neurologic complications is unknown. IAE may be accompanied by viral pneumonia (including occult pneumonia).

Infection Control

Infection control for prevention of nosocomial influenza is a fundamental part of clinical management in all health care settings, including chronic care facilities.* All health care personnel should receive annual influenza vaccination. For the 2011 to 2012 season, one U.S. survey reported that influenza vaccination coverage of health care personnel was 66.9 percent.[105] Patients with suspected or confirmed influenza should be isolated in single-patient rooms or cohorted with other influenza patients if single-room isolation is not possible. Standard, contact, and droplet precautions (i.e., gown, gloves, and surgical mask) are recommended for health care personnel providing care for patients with seasonal influenza and should be changed between patients. For aerosol-generating procedures, use of a fit-tested N95 respirator or equivalent is recommended.[114,756] Antiviral treatment of ill patients and postexposure antiviral chemoprophylaxis of exposed patients and health care personnel may be implemented, along with other prevention and control measures during nosocomial influenza outbreaks.[268,612] For patients with suspected or confirmed novel influenza A virus infection (i.e., zoonotic influenza resulting from infection with avian or swine influenza A viruses), a higher level of respiratory protection and use of eye protection may be indicated for routine clinical care if available, especially for patients with highly pathogenic avian influenza A (H7) or (H5) virus infections.[1] Avian influenza A (H7) viruses appear to have ocular tropism, and eye protection with goggles is recommended when providing care for patients with low-pathogenic or highly pathogenic avian influenza A (H7) viruses (e.g., H7N2, H7N3, and H7N7).[42] For patients with suspected or confirmed highly pathogenic avian influenza A (H7) or (H5) virus infections, especially severely ill patients, health care personnel should wear gowns, gloves, goggles, N95 respirator, or equivalent protection.[759] Close follow-up of contacts exposed within 2 m of a case of highly pathogenic avian influenza A (H7) or (H5) virus infection, including health care personnel, is recommended for at least 7 days after the last known exposure.[107] Severely ill patients with highly pathogenic avian influenza A (H5N1) virus infection can be isolated in a negative-pressure room, if available.[108,756] For all influenza patients, family members and visitors should be restricted, and caregivers should be equipped with the same level of personal protective equipment as indicated for health care personnel.

Outbreaks

In addition to nosocomial outbreaks, seasonal and pandemic influenza outbreaks affecting children can occur in

*References 80, 112, 192, 256, 268, 398, 449, 486, 591, 594, 612.

almost any setting. Outbreaks of influenza occur frequently among schoolchildren, resulting in high absenteeism.* Influenza outbreaks can occur in childcare centers.[372] Outbreaks in pediatric long-term care facilities can result in severe complications and deaths in children with disabilities.[112] During the summer months, influenza outbreaks among children attending camps can occur.[170,580] Cruise ship outbreaks of influenza can occur any time of the year and affect a wide age range.[705,730] Prevention and control of influenza outbreaks require a high index of suspicion for influenza and active surveillance for influenza-like illness and acute respiratory illness among children, adult caregivers, and visitors; influenza testing to confirm the outbreak; prompt implementation of infection control measures (i.e., isolation of ill persons and quarantine and surveillance of exposed); pharmaceutical (i.e., antiviral treatment of ill persons, antiviral chemoprophylaxis of exposed persons, and influenza vaccination of unvaccinated persons) and nonpharmaceutical measures (e.g., use of appropriate personal protective equipment); and close collaboration with public health personnel.

Influenza Vaccines

Vaccine Strain Selection

The WHO conducts biannual meetings to select the antigenic composition of the seasonal influenza vaccine virus strains for the Northern (February) and Southern (September) Hemispheres.[17,587] These decisions are based on antigenic characterization data on recently circulating influenza A and B virus strains worldwide produced by WHO Collaborating Centers, the availability of egg-grown virus isolates to serve as vaccine seed strains, growth properties, and other factors.[17,374] Vaccine manufacturers may substitute antigenically equivalent strains for those recommended by the WHO because of growth properties. Individual countries make the final vaccine strain decisions for licensed influenza vaccines. In the United States, influenza vaccine strain selection recommendations are made by the FDA's Vaccines and Related Biological Products Advisory Committee each February for the coming fall and winter influenza season. Vaccine strain selection is done in advance of the typical influenza season in temperate climate countries because of the long lead time needed for vaccine production using traditional methods of virus growth in embryonated hen's eggs. The process from influenza vaccine production to vaccine availability takes approximately 5 to 8 months for egg-grown vaccine viruses, and less time for tissue cell culture–derived vaccine viruses.[475,551]

Pediatric Influenza Vaccines

Most seasonal influenza vaccines produced worldwide to date are split virion or subunit, unadjuvanted, trivalent inactivated influenza vaccine (ITIV3). They contain two subtypes of type A viruses (H1N1 and H3N2) and at least one type B virus antigen. These are produced by growing a virus derived from an egg-adapted influenza virus (e.g., PR8 for type A and B/Lee for type B) that is genetically reassorted with two genes from the seasonal vaccine virus (HA and NA). Each of the three or more reassortant vaccine seed viruses are individually inoculated and grown in the allantoic sac of embryonated eggs, through essentially the same process that has been used for many decades. The viruses harvested from the allantoic fluid are inactivated, purified, disrupted into split virions or subunits, and then combined to produce vaccine containing two influenza A virus antigens (an H1N1 and an H3N2) and one influenza B virus antigen (or two influenza B virus antigens for quadrivalent vaccines). Each dose of vaccine contains a minimum of 15 μg of hemagglutinin for each of the three or four components and is given by intramuscular injection. In the United States, quadrivalent inactivated and quadrivalent live attenuated influenza vaccines are approved for use in children.

Inactivated influenza vaccine (IIV) is available as "preservative-free," containing zero or very low thimerosal levels, in prefilled syringes or small-volume vials, and in thimerosal-containing multidose vials. Whole virus vaccines are associated with greater reactogenicity versus split virion vaccines and are no longer available in the United States. It is impossible to become infected with influenza viruses from receipt of inactivated influenza vaccine. As of July 2013, quadrivalent inactivated influenza vaccine (IIV4) containing two influenza A and two influenza B virus antigens from two manufacturers was approved for use in children. An inactivated vaccine from tissue cell culture–derived viruses was approved in Europe in 2007 and for adults in the United States in 2012. Vaccines produced using tissue cell culture–derived viruses can be manufactured more rapidly than vaccine produced using egg-grown viruses. Advantages include higher purity yield of virus antigens, more reliable production, and avoidance of ovalbumin—eliminating the potential for severe egg-related allergic reactions in persons with egg allergies. However, use of tissue culture raises the issue of potential contamination with adventitious agents, including known and novel viruses that may not have a cytopathic effect, and the need to conduct a range of testing strategies to assess the presence of such adventitious agents.

Use of adjuvants enhances immunogenicity and antibody response, especially in young infants and for influenza B antigens, allows for use of lower vaccine antigen concentration (dose-sparing), and promotes a broader cross-protective immune response.[183,718] Induction of broader cross-immunity may provide an advantage during seasonal influenza epidemics in which significant antigenic drift occurs (i.e., mismatch between vaccine strains and circulating strains). As of 2013, no adjuvanted influenza vaccines were approved in the United States, but an adjuvanted inactivated trivalent influenza vaccine has been available in some European, Latin American, and Asian countries. Vaccines containing oil and water adjuvants, MF59 or ASO3, are available from different manufacturers.

Live attenuated influenza vaccine (LAIV) is produced from genetic reassortment using separate influenza type A and B "master" strains that were serially passaged in eggs and attenuated at lower temperatures

*References 86, 88, 233, 235, 236, 406, 471, 778, 794.

("cold-adapted") and the HA and NA of seasonal vaccine viruses and grown in the allantoic sac of embryonated eggs.[439] The three or four vaccine strain components are then combined into trivalent (LAIV) or quadrivalent (LAIV4) vaccines. LAIV viruses replicate only at temperatures typical of the nasal passages, which are lower than the internal body temperature in the lower respiratory tract. Each dose of LAIV contains a minimum of 15 μg of HA of each of the strain components and is administered as an intranasal spray. Replication of the live attenuated viruses in the nasopharynx induces local mucosal IgA immunity and a systemic immune response (i.e., subtype-specific neutralizing antibodies). LAIV viruses can replicate and be detected in nasal specimens for several days to longer periods (i.e., 7 to 21 days),[61,448] but secondary transmission is rare. Therefore, testing of nasal specimens collected within a few days or longer after LAIV administration may be positive for influenza viruses of LAIV origin.[7] Transmission of LAIV viruses is rare, but theoretically possible. A quadrivalent LAIV (LAIV4) was approved in 2012 for healthy children 2 years of age and older to be available during the 2013-2014 influenza season in the United States and will replace trivalent LAIV. This quadrivalent vaccine contains two influenza A (an H1N1 and an H3N2) and two influenza B (a B/Victoria lineage, and a B/Yamagata lineage) viruses. An advantage of the quadrivalent vaccine is that virus antigens from both currently circulating lineages of influenza B viruses (i.e., B/Victoria-like and B/Yamagata-like) are included versus only one B virus lineage antigen for trivalent vaccines.[573]

Monovalent pandemic influenza vaccine was used in many countries during the 2009 H1N1 pandemic, including unadjuvanted and adjuvanted inactivated vaccines (both tissue cell culture-derived and egg-grown) and LAIV. In the United States, inactivated unadjuvanted egg-derived monovalent 2009 H1N1 split virion vaccine became available after the second pandemic wave had peaked in the fall of 2009. The same 2009 H1N1 virus antigen used in the monovalent pandemic vaccine was included in the trivalent seasonal influenza vaccines for the Southern and Northern Hemispheres beginning in 2010.

Vaccine Immunogenicity

Correlates of humoral immune protection for inactivated influenza vaccination include measurement of serum HAI antibodies or, less commonly, neutralizing antibodies. In general, an HAI titer of 40 or greater is considered to correlate with immunity. However, in one study, much higher HAI antibody titers were found to correlate with immune protection after TIV (IIV3).[57] Inactivated influenza vaccines are less immunogenic in very young infants in contrast to those 6 months of age and older, especially when maternally derived antibody is present, and are more immunogenic for influenza A versus B viruses in young children.[179,255,724] Immunogenicity in inactivated influenza vaccine studies can be assessed by the postvaccination geometric mean antibody titer rise relative to the prevaccination geometric mean antibody titer, which can provide a meaningful estimation of the robustness of response to vaccination. In persons with prevaccination antibodies, immunogenicity is generally assessed by the mean fold increase in HAI antibody titer (i.e., postvaccination divided by prevaccination titer), or seroresponse rate (i.e., proportion of vaccinated individuals with a fourfold or greater rise in antibody titer from prevaccination to postvaccination sampling), where seronegative individuals achieve an antibody titer of 40 or greater. The proportion of vaccinated individuals that achieve an HAI antibody titer of 40 or greater is often used to evaluate vaccine immunogenicity for regulatory purposes.

Two doses of inactivated influenza vaccine administered the same season 1 month or longer apart are needed for priming in previously unvaccinated children 6 months through 8 years of age. Two doses given 1 month apart are immunogenic in infants 6 to 23 months of age. When vaccine strains are changed, children 6 months to 9 years of age who received only one dose in their first year of vaccination and one dose the following year are less likely to achieve protective antibody titers in contrast to children who received two doses their first vaccination year.[181,497,725] When vaccine strains are unchanged in consecutive seasons, priming children 6 to 23 months of age with one dose in the spring and one dose in the fall has similar immunogenicity to two doses given in the fall,[180] but estimated vaccine effectiveness in one study was higher for the fall two-dose regimen.[9] Immunogenicity, safety, and reactogenicity of a mammalian cell culture–derived IIV in children 9 to 17 years of age were comparable to those of egg-grown TIV (IIV3).[715]

Vaccination with LAIV may produce a minimal HAI antibody response and the correlates of cellular immunity are not well-established. LAIV induces $CD4^+$, $CD8^+$, and T helper cell responses.[295] Data for LAIV also suggest that two doses 1 month apart are also needed for priming in young children who have not received any influenza vaccination. Immunogenicity and safety of quadrivalent LAIV was shown to be noninferior to trivalent LAIV.[59]

Vaccine Safety

Influenza vaccination is generally safe in children, including in infants 6 months of age and older, with few serious adverse events in randomized controlled trials or postmarketing surveillance studies.* The most common adverse events reported are self-limited local injection site pain and induration. In a comprehensive review of the evidence on influenza vaccine–associated adverse effects, a U.S. Institute of Medicine committee concluded that the evidence was insufficient to assess the risk for most serious influenza vaccine–associated adverse events, but that anaphylaxis may occur, TIV (IIV3) in children and adults is not associated with exacerbation of asthma or reactive airway disease and is not associated with Bell palsy.[647] Potential serious vaccine-associated adverse events are reported to the Vaccine Adverse Event Reporting System.[483] No increases were noted in neuropsychological outcomes among children at 7 to 10 years who had been exposed to thimerosal-containing vaccines,

*References 212, 231, 241, 262, 466, 483, 583, 629.

including some influenza vaccines.[673] The risk for Guillain-Barre syndrome (GBS) after influenza vaccination was very low, but a slight increase was noted in recipients of monovalent 2009 H1N1 vaccine,[157,244,747] but not in 2009 H1N1 antigen-containing seasonal influenza vaccine.[681] No increased risk for GBS from adujvanted 2009 H1N1 vaccine was found in a European case-control study.[165] Although GBS was observed after the 1976 and 1977 swine influenza vaccination in the United Sates at a case frequency of 1/100,000 vaccinated persons, GBS has rarely been observed in children associated with influenza vaccination.[597,598] Influenza vaccination has been shown to have a protective association for GBS.[807] Notably, influenza virus infection has been associated with GBS in adults.[624]

Egg-derived influenza vaccines may contain a very small amount of ovalbumin and are thought to be safe to administer to children who have experienced only hives after egg exposure, with monitoring for at least 30 minutes after vaccination by a health care provider who is familiar with and can treat manifestations of egg allergy.[111] Children with more serious allergic reactions to egg should be referred to a physician with expertise in management of allergic conditions for risk assessment before vaccine administration.[111]

In 2010, an increase in febrile reactions and febrile seizures in children younger than 5 years of age was first noted in Western Australia after receipt of an Australian TIV (IIV3).[240] Studies indicated that this was associated with two IIV3s, Fluvax and Fluvax junior, and febrile reactions in young children were also noted in New Zealand with these vaccines.[22,355,552] In the United States, use of IIV3 produced from the same manufacturer was not recommended since 2010 for use in children younger than 9 years of age.[98] No evidence of any increase in febrile seizure events related to seasonal influenza vaccination of young children before 2010 was identified in the United States.[75] A slight increase in febrile seizures was noted with first-dose IIV3 in children 6 to 59 months of age in the United States, but the risk for febrile seizures was substantially higher when TIV was coadministered with PCV13.[687] Given the benefit of these vaccines to prevent morbidity resulting from influenza and pneumococcal disease, no changes in recommendations were made for IIV3 or PCV13. A previous study had reported an increase in local injection site and systemic reactions with IIV3 and pneumococcal conjugate vaccines versus either vaccine plus placebo.[328]

During the 2000 and 2001 influenza season in Canada, cases of self-limited bilateral red eyes, facial edema, or respiratory symptoms (i.e., oculorespiratory syndrome) were observed, beginning within 24 hours of receipt of one manufacturer's IIV3.[626] This syndrome has not been observed in the United States.

Vaccination with one manufacturer's adjuvanted (ASO3) monovalent inactivated 2009 H1N1 vaccine was associated with narcolepsy in children and adolescents in Finland and Sweden, but not with adjuvanted or unadjuvanted 2009 H1N1 antigen-containing vaccines in other countries.[185,186,513,542] Narcolepsy seasonality has been observed with an increase in cases during the 2009 H1N1 pandemic.[263]

LAIV is well tolerated, with few serious adverse events in young and older children and slight increases in nasal discharge or congestion, vomiting, abdominal pain, fever, and muscle aches generally associated with the first dose in young children.[47,555] A community-based nonrandomized study in healthy children 18 months to 18 years of age found no increased risk for medically attended post-vaccination events in 42 days after vaccination or for asthma in 14 days after vaccination.[554] One RCT reported an increase in reactive airway disease in children younger than 36 months of age.[51] One study of LAIV versus TIV (IIV3) in children 2 to 5 years of age with mild to moderate asthma or prior wheezing from two multinational RCTs did not find any increases in wheezing, lower respiratory tract illness, or hospitalization in LAIV recipients, but increases were noted in upper respiratory tract symptoms and irritability.[12]

Influenza Vaccine Efficacy

Results of influenza vaccine efficacy studies can vary depending on the defined outcomes (e.g., virus culture–confirmed or RT-PCR confirmed influenza, otitis media, or clinically diagnosed influenza illness). An updated systematic review concluded that influenza vaccines are efficacious in prevention of influenza in children 2 years of age and older but that limited evidence was available for those younger than 2 years.[333] Most RCTs have shown lower efficacy of TIV in children younger than 2 years of age and higher efficacy of IIV3 in children 2 years or older. Another review reported that the efficacy of influenza vaccination against laboratory-confirmed influenza was 67 percent and against otitis media 51 percent.[451] Both LAIV and IIV3 have efficacy versus placebo, respectively, and have similar efficacy to each other against influenza-associated otitis media.[60]

A systematic review and meta-analysis of LAIV reported pooled efficacy of 83 percent (95% confidence interval, 69%-91%) against laboratory-confirmed influenza in children 6 months to 7 years of age.[528] In the pivotal RCT, LAIV was 93 percent efficacious versus placebo against culture-confirmed influenza in children 15 to 71 months of age.[46] LAIV was more efficacious than TIV (IIV3) in RCTs among children 6 to 59 months of age[44] and those 6 to 71 months against culture-confirmed influenza.[13,24] One RCT in children 6 to less than 36 months found very high efficacy of LAIV against the influenza viruses studied, with higher efficacy against culture-confirmed influenza A versus influenza B virus infections.[716] One RCT in children 6 to less than 36 months of age attending daycare found an efficacy of 85 to 89 percent versus placebo.[716] In one open-label RCT of LAIV versus IIV3 among asthmatic children 6 to 17 years of age, LAIV showed greater efficacy than IIV3 against virus culture–confirmed influenza and was well tolerated, with no evidence of increases in adverse pulmonary outcomes.[204] LAIV was substantially more efficacious versus placebo in children 15 to 71 months of age against culture-confirmed influenza.[43] In one study, LAIV provided protection against an antigenically drifted H3N2 virus strain not included in the vaccine.[45]

Influenza Vaccine Effectiveness

The effectiveness of seasonal influenza vaccines varies from year to year and depends especially on the antigenic match between vaccine strains and the predominant circulating influenza A and B virus strains.[39,279] Ideally, multiyear assessments of influenza vaccine effectiveness are more informative than studies based on a single season and should use an outcome of laboratory-confirmed influenza virus infection. The current gold standard outcome for such studies is RT-PCR–confirmed influenza versus a RT-PCR influenza "test negative" comparison group with influenza-like illness. A case-control study design has been used to assess influenza vaccine effectiveness for outpatients and hospitalized children. Young children who received only one dose of TIV (IIV3) in the first year of vaccination did not have reductions in outpatient visits for influenza-like illness or laboratory-confirmed influenza.[9,578,616] IIV3 had effectiveness of 56 percent in fully vaccinated children 6 to 59 months of age who were not previously vaccinated, but was not effective in children who had received only one dose.[638] One study reported vaccine effectiveness of 42 to 69 percent in Japanese children 6 months to 6 years of age over a 6-year period for positive rapid influenza test outcomes.[348] One case-control study reported a substantially lower risk for medically attended laboratory-confirmed influenza in vaccinated versus unvaccinated U.S. children 6 to 59 months of age during 1999 to 2007.[338] During seasons with a suboptimal antigenic match between vaccine strains and circulating influenza virus strains, IIV3 effectiveness was poor in children 6 to 59 months of age.[658] In seasons in which influenza vaccines were well matched to all three circulating influenza virus strains, vaccine effectiveness of 69 percent (95% CI, 56% to 77%) was found in children 6 months to 8 years of age using a case-control test-negative study design with RT-PCR–confirmed influenza as the outcome.[684] Unadjuvanted, inactivated monovalent 2009 H1N1 effectiveness in the United States was 62 percent (95% CI, 25%-81%) in all ages and 32 percent in children 6 months to 9 years of age.[246]

Economic Studies of Influenza Vaccination

Multiple factors influence the economic impact (e.g., cost-effectiveness, cost-benefit, and cost-utility analyses) of pediatric influenza vaccination, including the cost of vaccine (e.g., inactivated versus LAIV); vaccine administration costs; the costs associated with vaccine adverse events; the clinical illness attack rate, which is highest in young children (variable from year-to-year); whether a child is at higher risk for severe illness complications (i.e., has underlying comorbidities or is very young); vaccine effectiveness (varies from year-to-year depending on the match between circulating strains and vaccine strains); and the direct medical care costs associated with treatments.[433,501,506,564,629] Although death is a rare outcome of influenza among children, the value placed on a death or a severe complication of influenza in a child can be an important factor in overall economic costs of influenza, and high costs are associated with hospitalization, although the greatest direct cost is from outpatient clinic and emergency medical care for young children.[189,260,357,562] Most economic studies have found that influenza vaccination of healthy children is cost-saving or cost-effective, with higher benefit in children who are at increased risk for influenza complications.* Few economics studies have considered the indirect benefits of pediatric influenza vaccination to prevent influenza in secondary household members, school and social contacts, and the community, suggesting that economic benefits may be underestimated.[234,237,313,420,553]

Maternal Vaccination and Benefits

One RCT and multiple observational studies have reported the clinical benefit of maternal influenza vaccination on birth outcomes and prevention of influenza in infants up to 6 months of age who were born to women vaccinated during pregnancy.[50,175,644,792] Infants born to women who did not receive influenza vaccination during pregnancy had lower birth weight and higher likelihood of prematurity than babies born to mothers who had received influenza vaccination during pregnancy.[521,644] The clinical benefit observed in infants born to vaccinated mothers was correlated with higher levels of maternally derived HAI antibodies in cord blood and with longer duration of detection of HAI antibodies in infant sera.[175,643] Although the kinetics of passively transferred antibodies is not well understood, existing data suggest a drop off of HAI antibodies from 2 to 3 months to 6 months of life. The role of breast-feeding and contribution of IgA antibodies is unclear. In the United States, influenza vaccination coverage of pregnant women during the 2011 and 2012 season was 47 percent in one survey, with 36.5 percent vaccinated during pregnancy.[106] Overall, available data suggest that in addition to prevention of influenza in pregnant women, maternal influenza vaccination also results in improved birth outcomes and reduction of influenza in infants to 6 months of life. This suggests that one important strategy to prevent influenza in infants younger than 6 months of age who are contraindicated for influenza vaccination is to administer influenza vaccine to pregnant women during influenza season.

Prevention of Influenza in the Intrapartum Setting and Breast-Feeding

A pregnant woman symptomatic with influenza in the intrapartum period poses a risk for influenza virus transmission to the newborn infant through direct and close exposure. Although data are lacking on the risk and best prevention measures, guidance has been developed to reduce transmission while balancing the importance of preserving the maternal–infant bond and breast-feeding.[571] These emphasize adhering to recommended infection control precautions (i.e., isolation and droplet precautions) for influenza prevention in the labor, delivery, recovery, and postpartum settings and consideration of temporary separation of the newborn infant on

*References 229, 289, 433, 452, 595, 596.

a case-by-case basis until at least 24 hours after fever resolution. A healthy caregiver can feed the infant the mother's expressed breast milk or formula. If co-location is unavoidable, the infant should be kept at least 2 m away from the mother. Limited data suggest that breast milk from a woman treated with oseltamivir will contain low levels of oseltamivir and oseltamivir carboxylate (metabolite) which do not pose a risk for the infant.[245,665,740] The infant should be monitored closely for signs and symptoms of influenza. At discharge, the family should be educated about prevention of influenza virus transmission to the infant at home. Influenza vaccination of all household members 6 months of age and older and caregivers of an infant younger than 6 months ("cocooning strategy") is recommended.[571]

Vaccine Production and Availability

Once the WHO issues vaccine strain selection recommendations for the upcoming hemisphere's influenza season, manufacturers commence with production of influenza vaccines. For egg-grown vaccine viruses, the manufacturing process takes approximately 5 to 8 months until vaccine is available, depending on growth properties of vaccine virus strains, quantity produced, vaccine lot approvals, and other factors. During the 2004 and 2005 season in the United States, one of the two manufacturers experienced problems with bacterial contamination and did not provide vaccine; therefore 50 percent of the projected vaccine supply for that season was lost and high-risk groups were prioritized to receive available vaccine.[95,96] In the United States, influenza vaccine generally becomes available in the late summer and early fall, with production and distribution continuing into the late fall and winter. In the United States, influenza vaccine is given an expiration date of June 30 each year. In Northern Hemisphere temperate climate countries, the optimal period for influenza vaccination is during the fall, starting in September to December. In Southern Hemisphere temperate climate countries, the vaccination period is typically March to June. Influenza vaccination can continue in a community for longer periods if local influenza activity has not peaked. In tropical and subtropical regions with different influenza virus seasonality, including countries with bimodal peaks in influenza activity or with year-round activity, decisions about when to start influenza vaccination and which vaccine formulation to use should be based on analyses of multiple years of local surveillance data. A wide range of influenza vaccines are available from various manufacturers, with different age approvals.

Vaccine Recommendations

Annual influenza vaccine recommendations in the United States are issued by the Advisory Committee on Immunization Practices (ACIP).[100] The United States is the only country that has recommended annual influenza vaccination of all persons 6 months of age and older since 2010.[99,111,203] Before 2010, influenza vaccination of children was recommended for children 6 to 59 months of age and for children 6 months of age and older with certain chronic medical conditions. In other countries, priority is placed on vaccination of high-risk groups such as elderly persons, and children and adults with certain chronic underlying conditions. In 2012, the WHO Strategic Advisory Group of Experts recommended that all member states should prioritize annual influenza vaccination of pregnant women and children 6 to 59 months of age and especially those 6 to 23 months.[763] This recommendation was based on available global influenza burden data.

Influenza vaccine coverage among children in the United States has increased in recent years as recommendation for pediatric age groups expanded, with higher coverage in younger children, but remains suboptimal.[603] For the 2011 and 2012 season, estimated overall influenza vaccination coverage in children 6 months to 17 years of age was 51.5 percent, including 74.6 percent for those 6 to 23 months of age, 63.3 percent for those 2 to 4 years, 54.2 percent for those 5 to 12 years, and 33.7 percent for those 13 to 17 years.[103] School-based vaccination is a strategy to increase influenza vaccine coverage among schoolchildren,[142,174,307] which may have direct and indirect benefits.[237,249,559]

Influenza vaccine is not approved for infants younger than 6 months of age because of poor immunogenicity. Standard-dose preparations of inactivated vaccine contain 7.5 μg HA antigen per vaccine strain (for <36 months) or 15 μg of HA antigen (for ≥36 months) per vaccine strain. For young children 6 months through 8 years of age who have not previously received influenza vaccine, two doses of inactivated seasonal influenza vaccine administered 1 month apart are recommended. For otherwise vaccine-naïve healthy children 2 years through 8 years of age, two doses of seasonal LAIV 1 month apart are recommended. For children younger than 9 years of age, if they have previously received two doses in 1 year, a single dose of seasonal influenza vaccine is recommended each year. Any child 9 years of age or older, even if not previously vaccinated, requires a single dose. Children aged 6 months to less than 3 years require 0.25 mL per dose (7.5 μg of H antigen content per vaccine strain), and those 3 years of age and older require 0.5 mL per dose (15 μg of HA antigen content per vaccine strain). Children with a history of severe egg allergies (anaphylaxis) should be evaluated by an allergist before egg-derived influenza vaccine is administered. All influenza vaccines approved for persons 6 months of age and older in the United States are unadjuvanted vaccines.[99,111]

Vaccines in Development

Influenza vaccines approved for adults in the United States include intradermal inactivated vaccine for persons 18 to 64 years of age (approved in 2011), tissue cell culture–derived trivalent inactivated vaccine (ccIIV3) for persons 18 years of age and older (approved in 2012), a recombinant DNA hemagglutinin vaccine (RIV) using an insect cell line and a baculovirus vector for persons 18 to 49 years of age (approved in 2013), a live attenuated vaccine for healthy nonpregnant persons up to 49 years of age (approved in 2003), and a high-dose antigen vaccine for persons 65 years of age and older (approved

in 2009). Adjuvanted inactivated influenza vaccines are approved for persons 65 years of age and older in some countries. In addition to adjuvanted vaccine and tissue cell culture–produced vaccines,[551,717] novel vaccines in development include virosomal vaccines, virus-like particles, insect cell culture–derived vaccines, recombinant plant cell–derived vaccines, adenovirus-vectored vaccines, DNA vaccines, and universal vaccines that target conserved epitopes such as the M2 extra domain or HA stalk domain.*

Nonpharmaceutical Interventions

Nonpharmaceutical interventions can be an adjunct to pharmaceutical interventions in the prevention of influenza or can be the only preventive measures if influenza vaccine and antiviral medications are not available, for both seasonal influenza epidemics and pandemic influenza.[136,137,621,651] Use of facemasks to prevent secondary household influenza virus transmission is of variable efficacy in a small number of studies, with benefit when mask-wearing is started by exposed family members within 36 hours after an index case's illness onset.[136,137,621,651] Soap and water and alcohol-based hand rub preparations are effective at reducing influenza A viruses on human hands.[243] Overall, the effectiveness of hand hygiene to reduce influenza virus transmission likely varies by the setting, context, and compliance.[731] One RCT in Egyptian schoolchildren found that a twice-daily hand washing intervention resulted in a reduction of rapid influenza diagnostic test confirmed influenza by 50 percent in contrast to controls.[661] A cluster-randomized hand washing study in U.S. elementary schoolchildren did not find a reduction in overall RT-PCR–confirmed influenza, but reported a reduction of total absences by 26 percent and in laboratory-confirmed influenza A by 52 percent versus the nonintervention group.[641] Hand washing has been demonstrated to have efficacy in reducing acute lower respiratory tract infections in young Pakistani children.[432] Other nonpharmaceutical community interventions include school closures, but must be implemented early for greatest effectiveness.[90,173,769]

Pandemic Preparedness Countermeasures

Pharmaceutical (medical) countermeasures for pandemic influenza preparedness include antiviral drugs and vaccines (and adjuvants) against novel influenza A viruses. Many countries have stockpiled oral formulations of the NA inhibitor antiviral drug oseltamivir, and some have also stockpiled inhaled zanamivir. Such antiviral drug stockpiles need to be maintained and replenished, depending on shelf-life.[543] Some countries have stockpiled vaccines against different H5N1 viruses. Because of the dynamic nature of H5N1 viruses circulating among poultry and other birds worldwide, such H5N1 vaccine candidates need updating.[762] Similarly, candidate vaccines against different avian (H7, H9) and variant (H3N2v) viruses are under development.[761,762] Technologies to rapidly expand vaccine production capacity (e.g., tissue cell culture) in the event of an influenza pandemic are also in development.

Update on H7N9 at Time of Printing

On March 31, 2013, the first human infections with a novel avian-origin influenza A (H7N9) virus were reported in China to the WHO, raising global public health concerns.[221,703] These infections were identified in critically ill adults with severe pneumonia in eastern China. As of July 2013, 132 confirmed cases of H7N9 virus infection with 43 deaths had been identified in 10 different areas of China, and one additional case was identified in Taiwan. Most cases experienced febrile respiratory illness that evolved into a rapidly progressive pneumonia and respiratory failure, and some patients experienced multiorgan dysfunction. Most human infections were linked to recent poultry exposures, including at live animal markets. Although some clusters of illness were identified in family contacts of confirmed cases in which limited, nonsustained human-to-human transmission of H7N9 virus likely occurred, no evidence was found of sustained human-to-human transmission.[411] The latest information on human infections with H7N9 virus from the WHO is available at http://www.who.int/influenza/human_animal_interface/influenza_h7n9/en/index.html.

Latest Information on Influenza

For updated information on influenza surveillance and circulating influenza viruses, novel influenza A viruses, and recommendations for prevention and control of influenza, including guidance on the use of influenza vaccines and approved antivirals, clinicians are referred to sources such as the CDC (http://www.cdc.gov/flu/professionals/index.htm) and WHO (http://www.who.int/influenza/en/index.html).
